18.1 SUMMARY

The reliable reporting of data from the quantitative analysis of drugs and their metabolites is the backbone of drug discovery and development; therefore, the bioanalytical methods that produce the data should be sufficiently accurate and reproducible. This chapter provides an overview of different technologies that offer opportunities to improve the data quality and efficiency of method development, method validation, and biological sample analysis.

The regulatory requirements of data quality are reviewed. Specifically, regulators require that bioanalytical methods be validated to ensure accurate and precise results. The quality of an analytical method is normally assessed by the performance of standards and quality control samples (QCs). Current regulatory guidance recommends an acceptance criterion of 15% for accuracy and precision of all standards and QCs, with the exception of the lower limit of quantitation (LLOQ), where the acceptance criterion is increased to a 20% deviation.

Technologies that improve sample cleanup are reviewed because data quality is the sum of effective sample preparation and appropriate chromatographic separation of endogenous matrix components. In other words, poor sample preparation cannot be overcome by high performance liquid chromatography (HPLC). Inadequate sample cleanup and chromatography often leads to matrix effects that are revealed by irreproducible results for some bioanalytical methods. Plasma phospholipids have been identified as playing a major role in causing matrix effects in liquid chromatography-mass spectrometry (LC-MS) bioanalysis. Therefore, in order to minimize the potential for matrix effects, the removal of phospholipids is an important component of any sample cleanup process. Moreover, the process of sample extraction is often a rate-limiting step in the workflow associated with quantitative bioanalysis.

Of the three commonly used extraction techniques for plasma or serum samples, protein precipitation ("dilute and shoot") is the least suited for assays that require low levels of quantitation because of its susceptibility to ion suppression and matrix effects from remaining endogenous components. Liquid-liquid extraction and solid-phase extraction (SPE) are techniques that offer much cleaner sample extracts that in turn serve to make the method more robust and scalable. SPE is particularly powerful in this regard because of its unique ability to utilize a variety of retention mechanisms. The most widely used SPE sorbent phases are those that are based on retention and elution mechanisms that involve polar and/or nonpolar interaction mechanisms. To fulfill the requirements of selectivity and retention, vendors now offer mixed-mode sorbents that afford hydrophobic and hydrophilic interactions in addition to ion exchange. With mixed-mode strong cation- or anion-exchange SPE, significant cleanup is achieved during the 100% organic wash step, where phospholipids bound by reversed-phase interactions are removed along with any other neutral hydrophobic interference.

To reduce time and effort, on-line sample preparation (direct sample injection), using either turbulent flow chromatography (TFC) columns or single-use SPE-packed cartridges, is a viable alternative to off-line sample preparation.

A practical review of chromatographic principles is provided. It is important to maintain chromatographic resolution as flow rates are increased or column particle sizes are decreased; otherwise, no improvement in productivity is realized. The long-term trend toward ever smaller column particle sizes is an effort to achieve the same performance as is possible with larger particles but in a shorter analysis time. The development and application of small particles (sub-2- μm particles) and fused-core (pelicular) high resolution columns is discussed.

Although increasing resolution by using smaller particles is a common approach to enabling faster separations, selectivity has the greatest effect on resolution. Selectivity is governed predominantly by analyte interactions with both the stationary and mobile phases. Of these, the stationary phase is the most important for chromatographic resolution. Selectivity differences may be brought about by changes in hydrogen bonding, dipole-dipole interactions, and/or ionic interactions with the stationary phase. The ionization state of an analyte resulting from the pH of the mobile phase may also alter the degree of interaction with the stationary phase. Column temperature is another easily adjustable parameter that can provide alternative selectivity leading to increased resolution and an overall reduction in analysis times. The conformational changes that occur with long-chain alkyl stationary phases as a function of temperature can produce selectivity differences among analytes.

Parallel or multiplexed LC-MS/MS systems that can analyze the eluent from several LC systems using a single mass spectrometer are a solution to support high throughput production of quality data. Multiplexed systems with ultrahigh performance capable chromatography systems are available. Included in some systems is the ability to alternate between on-line extraction methods and conventional LC methods.

The presence of unidentified metabolites can lead to inaccurate measurement of analyte concentrations because of ionization suppression, interference in peak integration, or, most problematic, in-source regeneration of the parent drug from phase II metabolites, as the metabolites are not present in the calibration standards and QCs. The importance of chromatographic separation in quantitative analysis should never be overlooked.

Minimizing the risk factors that can affect method reproducibility is an important aspect of developing a quality method. Developing a quality method requires that sufficient attention be given to the fundamentals of sample preparation and chromatography in the face of the never-ending drive for higher throughput.

18.2 INTRODUCTION

Analytical methods employed for the determination of drugs and metabolites in biological matrices such as urine, plasma, serum, and even tissue are essential throughout drug discovery and development. Over the last decade, the development of LC-MS technology has revolutionized bioanalysis. The combination of LC and MS/MS offers unparalleled sensitivity and specificity few other techniques can match [1–3]. Indeed, there was a period following the introduction of LC-MS/MS instrumentation that sample cleanup and high resolution chromatography were thought to be superfluous [4,5]. Fortunately, practitioners soon learned that adequate sample cleanup and chromatographic retention were needed to separate matrix interferences and biotransformed products away from the analyte to obtain better specificity, accuracy, and precision for drug determination in biological matrices [6–9]. Two review articles summarize the literature related to the development of fast LC-MS methods [10] and bioanalytical sample preparation [11].

Despite the advantages offered by the LC-MS/MS technology, the development of rugged and reproducible methods for bioanalysis remains a challenging endeavor. Indeed, there are reports that address the systematic troubleshooting of LC-MS/MS methods [12,13]. Therefore, the successful use of LC-MS/MS for bioanalysis requires an understanding of the mechanisms of various sample extraction processes and the underlying principles of both chromatography and mass spectrometry.

The reliable reporting of data from the quantitative analysis of drugs and their metabolites is the backbone of drug discovery and development. As the drug continues through development, the decisions become more critical; therefore, the bioanalytical methods that produce the data should be sufficiently accurate and reproducible. The regulatory agencies of different countries have their respective guidance documents describing the requirements for bioanalytical method validation and the application of these methods to routine drug analysis. For example, the FDA considers the quality of bioanalytical data generated during toxicology studies to be critical in determining the safety of a drug [14] and therefore requires that the bioanalytical methods be validated to ensure accurate and precise results [15–17]. Bioanalytical method validation is the

process that demonstrates that an analytical method used to quantify an analyte in a biological matrix is reliable, reproducible, and suitable for its intended purpose.

18.3 REGULATORY GUIDANCE FOR THE VALIDATION OF QUANTITATIVE CHROMATOGRAPHIC ASSAYS

The pharmaceutical industry is governed by enacted laws and regulations issued under those laws by regulatory agencies of many different countries. These regulatory agencies on occasion offer suggestions of best practices in the form of guidance documents that they will normally consider acceptable, if followed [17–20]. The FDA Guidance on Bioanalytical Methods Validation is one such guidance that describes best practices for the validation and subsequent application of bioanalytical methods [21]. Complementary guidance is available from the European Medicines Agency [22,23]. The fundamental parameters for method validation include accuracy, precision, selectivity, sensitivity, reproducibility, and stability [24–27]. The reader is directed to the chapter titled *Analytical Method Development and Validation in Accordance to the Regulatory Guidelines* for an in-depth discussion of the regulatory requirements associated with the application of bioanalytical methods.

The quality of an analytical method is normally assessed by the performance of standards and QCs. Current guidance recommends an acceptance criterion of 15% for accuracy and precision of all standards and QCs, with the exception of the LLOQ, where the acceptance criterion is increased to a 20% deviation. However, standards and QCs may not adequately reflect the composition of study samples from dosed subjects, that is, incurred samples. The limitation of using spiked control samples to assess “real” samples has been acknowledged for years, and there is general acceptance of the inherent risk of obtaining erroneous results. Confirmatory reanalysis of incurred samples is a recent best practice to determine the reproducibility of a method and ascertain the potential influence of metabolites, protein binding, sample homogeneity, and matrix effects otherwise not determined when using spiked standards and QCs [20,28,29]. Minimizing the risk factors that can affect method reproducibility is an important aspect of developing a quality method and is a primary focus of this chapter. Developing a quality method requires that sufficient attention be given to the fundamentals of sample preparation and chromatography in the face of the never-ending drive for higher throughput.

18.4 SAMPLE PREPARATION CONSIDERATIONS

As LC and MS technologies improve and analysis times reduce, the process of sample extraction becomes a rate-limiting step in the workflow associated with quantitative bioanalysis. For example, reducing overall cycle times is critical for clinical development when multisubject pharmacokinetic (PK) studies can generate a few thousand plasma and urine samples. Moreover, the development of drugs of ever increasing potency will continue to challenge the analytical chemist to lower the levels of quantitation (LLOQ). An LLOQ of 100 pg/mL is a common request for clinical development programs, and when this is coupled with the demand for lower sample volumes, the analytical chemist is well challenged.

Technologies for sample preparation have progressed in lock step with improvements in LC-MS/MS instrumentation. Robotic liquid handling systems with multiple probes for solvent and sample aspirating/dispensing in 96-well plate formats have been developed and commercialized to speed up sample preparation time [30–32]. Parallel processing of samples by protein precipitation or SPE can take anywhere from 10 min to an hour for a single 96-well plate.

The reader is directed to the chapter titled *Direct Biofluid Analysis Systems* for a more complete discussion of sample preparation.

18.4.1 Ion Suppression/Enhancement

A very common form of sample extraction for plasma or serum samples is acetonitrile precipitation of proteins followed by chromatographic separation using ballistic gradients on short analytical columns. Cycle times of <2 min are routine. However, it has become apparent that inadequate sample cleanup and chromatography often leads to, what is now termed, *matrix effects* that are revealed by irreproducible results for some bioanalytical methods [5,33]. Matrix effects cause either analyte ionization suppression or enhancement and occur when endogenous components coelute with the analyte [9,34–38]. The more common effect of ion suppression is observed primarily in electrospray ionization (ESI), where analyte ion signal is attenuated by competition from the ionization of bulk ions inside the solution droplets [39].

A number of techniques to visualize ion suppression have been proposed in the literature. The most widely adopted method for the qualitative assessment of matrix effects involves monitoring the MRM (multiple reaction monitoring) transition of a postcolumn-infused analyte while blank matrix is injected [36,40]. Ion suppression is revealed as dips in the constant background ion signal of the analyte. For the quantitative assessment of matrix effect, a different technique is used, wherein the response of the analyte spiked into extracted blank matrix is compared with that of the analyte spiked into matrix-free reconstitution solution [9,35,39,41,42].

Plasma phospholipids have been identified as playing a major role in causing matrix effects in LC-MS bioanalysis [43–45]. The two common structural classes of phospholipids are glycerophospholipids and sphingomyelins [46–48], and their concentrations in human plasma range between 1.6 and 3.0 mg/mL [49]. Although there is significant lipid variation within the population, because of diet and metabolic rate, phosphatidylcholine (PC) is the primary phospholipid circulating in plasma, accounting for about 60–70% of the total phospholipids [50–52]. As a zwitterion, PC can cause ion suppression in both positive and negative ESI modes because of its ability to ionize in both environments. Therefore, in order to minimize the potential for matrix effects, the removal of phospholipids is an important component of any sample cleanup process. The effectiveness of the cleanup can be monitored by using positive ESI selected reaction monitoring of m/z 184 $\rightarrow$ 184, with the precursor ion (m/z 184) generated in the source by collision-induced dissociation (CID) of phospholipids [53]. An alternative approach utilizes either positive ion neutral loss scans of 141 Da or a negative precursor ion scan of m/z 153 [54].

Considerable attention has been given to approaches for the removal of phospholipids during sample extraction. One report evaluated popular and commercially available ion exchange and mixed-mode SPE sorbents for their ability to remove

phospholipids. It was determined that reverse-phase retention mechanisms are detrimental in eliminating ion suppression caused by late-eluting phospholipids. If an analyte and its metabolites can be retained using an ion exchange mechanism alone, mixed-mode extraction phases should be avoided [55]. Moreover, it is recommended that elution of analytes be performed using aprotic solvents such as acetonitrile rather than using protic solvents such as methanol because of the increased solubility of phospholipids in the latter [56].

Sorbents containing lanthanide metal active surface elements were used successfully to remove phospholipids through a two-step cleanup process involving liquid–liquid extraction with methyl *tert*-butyl ether followed by SPE on a proprietary column [57–59]. Similarly, almost 99% of phospholipids were removed from serum by using cerium-modified columns [60]. More recently, a product (Sigma-Aldrich HybridSPE™) became available, which incorporates zirconia-coated particles. The product is available in a 96-well plate format and has demonstrated selective affinity toward phospholipids while remaining nonselective toward a range of basic, neutral, and acidic compounds [61]. More recently, Waters has introduced a sample preparation product called *Ostro*™ with a proprietary packing that selectively removes phospholipids while filtering precipitated proteins after protein precipitation.

It should not be forgotten that formulation excipients such as polyethylene glycol (PEG), sometimes administered in large quantities with the compound, can create ion suppression effects that are not present in control matrices [62–64]. Similarly, significant ion suppression was observed with a formulation containing polysorbate 80 (Tween 80®) [64,65].

Adequate sample cleanup along with sufficient chromatographic separation remain the primary tools to control matrix effects. Even then, it is important to adequately compensate for any alteration of ion signal by using an appropriate internal standard, most often a stable-isotope-labeled (SIL) analog of the drug [66]. An SIL internal standard is chemically identical to the analyte and is therefore considered to be essential in any quantitative assay that uses MS detection to avoid the influence of residual matrix effects on ionization efficiency [42,67]. Nevertheless, the use of an SIL internal standard does not always guarantee correction of matrix suppression [68]. The only way to avoid or minimize matrix effects is to develop a method that uses adequate sample cleanup and chromatographic resolution.

18.4.2 Orthogonal Approaches to Sample Preparation/Chromatography

Of the three commonly used extraction techniques, protein precipitation (“dilute and shoot”) is the least suited for routine plasma or serum assays with low LOQs (limits of quantitation) because of its susceptibility to ion suppression and matrix effects. For an alternative methodology, the reader is directed to the chapter titled *Analytical Method Development and Validation in Accordance to the Regulatory Guidelines* for a discussion on direct plasma analysis.

Liquid–liquid extraction and SPE are techniques that offer much cleaner sample extracts that in turn serve to make the method more robust and scalable. SPE is particularly powerful in this regard because of its unique ability to utilize a variety of retention mechanisms [69]. Moreover, the availability of SPE products in a 96-well format affords the opportunity for high throughput analysis using automated robotic liquid handlers with minimal operator intervention.

The most widely used SPE sorbent phases are those that are based on retention and elution mechanisms that involve polar and/or nonpolar interaction mechanisms. Specifically, sorbents that incorporate C₁₈ ligands are the most popular. However, the combination of polar and nonpolar retention mechanisms is also the least selective because nearly everything is retained from the biological matrices along with the analyte of interest. Although this retentiveness is sometimes an advantage in cases where metabolites and parent drug have very different polarities, in general, methods based on this type of interaction mechanism will then require more refined HPLC conditions to compensate for the lack of sample cleanup selectivity. On the other hand, a sorbent that utilizes an ion exchange interaction can be highly selective for molecules that contain functional groups capable of exhibiting either a positive or a negative charge under appropriate acidic or basic conditions [69]. The drawback with high selectivity is that, on occasion, metabolites with a significantly different pK_a from the parent drug will be difficult to isolate.

To fulfill the requirements of selectivity and retention, vendors now offer mixed-mode sorbents that afford hydrophobic and hydrophilic interactions in addition to ion exchange [55,70]. The advantage of incorporating both of these retention mechanisms is the potential to isolate structurally diverse analytes with adequate selectivity and high recovery [56,71]. Moreover, during mixed-mode strong cation- or anion-exchange SPE, significant cleanup is achieved during the 100% organic wash step, where phospholipids bound by reversed-phase interactions are removed along with any other neutral hydrophobic interference. With a reversed-phase only SPE, the final organic elution step simply releases the hydrophobic interferences along with the analyte of interest into the eluent.

Xue *et al.* [72] developed a simplified protein precipitation and mixed-mode cation-exchange SPE method for the extraction of a basic drug from human plasma. The concept was to directly transfer the protein precipitated supernatant onto an unconditioned Oasis[®] MCX μ Elution 96-well extraction plate. The simplified method offered equivalent performance and eliminated the time-consuming conditioning and rinsing steps.

18.4.3 Micro-Solid-Phase Extraction Tips

In order to eliminate the time-consuming steps of excess solvent evaporation followed by sample reconstitution, vendors have developed SPE products with smaller sorbent beds. Examples include the Waters Oasis μ Elution Plate and Omix[®] tips from Varian. SPE in pipette tips using monolithic sorbent technology is a particularly interesting development because it offers new automation possibilities not previously available [73,74]. Specifically, the elimination of a vacuum manifold enables true walkaway automation and the micro-SPE tip can perform exhaustive extractions simply by passing the sample back and forth over the sorbent bed. The micro-SPE tips have sufficient capacity to extract up to 100- μ L aliquots of plasma, and analytes can be eluted with as little as 60 μ L of organic solvent [75,76].

18.4.4 Turbulent Flow Extraction

To reduce time and effort, on-line sample preparation (direct sample injection) based on TFC offers an alternative and TFC on-line with LC-MS/MS has demonstrated its

utility and potential in the bioanalytical support of preclinical [77–80] and clinical studies [81–83].

Under conditions of high linear flow rates in columns packed with large, irregularly shaped particles ranging in size from 35 to 75 μm , the solvent flow profile will change from laminar to turbulent. Under the conditions of turbulent flow, low molecular weight molecules will diffuse faster into particle pores than larger molecular weight molecules. The practical implication is that biological samples can be injected directly onto a column and small molecules are retained at the column head while large macromolecules, such as proteins, and other unretained polar analytes, wash away. This is a highly effective technique to conduct on-line sample extraction [84–86].

Typical conditions for TFC involve flow rates above 4 mL/min with 10 mm i.d. columns and above 1 mL/min for 5 mm i.d. columns. For efficient extraction of analytes, the stationary and mobile phases selected need to provide a retention factor of at least 50 column volumes, preferably 100–200 column volumes [87–90].

Turbulent flow on-line extraction can be performed with two different configurations. For single-column methods [91], samples are loaded onto the column under turbulent flow conditions and then analyte elution occurs with a mobile phase of suitable strength under laminar or turbulent flow conditions. The peak capacity of the chromatographic separation can be low because the same solvent is used for both extraction and separation. Moreover, the high flow rates require splitting of the effluent before introduction into the ion source of a mass spectrometer.

The preferred configuration involves two columns; that is, samples are retained on a turbulent flow column, while proteinaceous material is diverted to waste and then the desired analyte(s) is eluted onto an analytical column (Figs. 18.1 and 18.2) [88]. The eluent is transferred through a tee to the analytical column into which the analytical

Figure 18.1 Turbulent flow extraction. Cohesive Technologies' "Quick Elute" program showing equilibration and loading steps.

Figure 18.2 Turbulent flow extraction. Cohesive Technologies' "Quick Elute" program showing the elution step.

pump delivers a weak mobile phase at a higher flow rate relative to the extraction flow to focus analytes on the analytical column [92]. In general, the extraction flow rate in the mixing step needs to be minimized in order to maintain the desired focusing effect [93]. Once the sample is transferred, the compounds are eluted and separated with a gradient or step elution on the analytical column. Dual-column extraction normally provides better chromatographic separation and peak shape than single-column methods. It is worth noting that to increase the extraction column lifetime and avoid column and system clogging, samples should be diluted or even extracted before injection.

18.4.5 On-Line SPE

Another alternative to be considered for automated on-line SPE is the SymbiosisTM system from Spark Holland. The Symbiosis system evolved from earlier ProspektTM systems and consists of a RelianceTM autosampler, a dual high pressure dispenser (HPD) solvent delivery system with six-port valves, a gradient pump set, and dual automated SPE cartridge exchange (ACE) system. Significantly, the system uses single-use (i.e., disposable) SPE cartridges, thereby reducing the potential for column and/or system clogging. Samples do not normally require sample dilution before injection.

The automation features offered by the Symbiosis system have allowed for automated and unattended method development that has proven very useful for rapid method development of robust assays [94]. The authors were able to complete method development within 4 h in a fully automated mode.

The Symbiosis system has also been used to provide a fully integrated approach to bioanalysis [95–97]. The Vial to FileTM process involves placing study samples into

an autosampler and then all subsequent operations related to data generation occurs in a hands-free, 21CFR11 compliant environment. Custom-designed sample vials from Sarstedt that incorporate septum pierceable caps were used to provide cryogenic storage of unknowns and compatibility with the Symbiosis autosampler. The extraction protocol featured microliter pickup of internal standard concurrent with the sample aliquot.

A recent application of the Symbiosis system is on-line extraction of dried blood samples using sorbent sampling cartridges [98,99]. The technique requires the application of 5–10 μL of blood onto a fibrous material packed into a Symbiosis compatible cartridge. Blood samples absorbed on these cartridges are subsequently eluted on-line using the Symbiosis system for SPE and LC-MS/MS analysis. The continued development of this strategy could result in a significant decrease in the use of animals in drug development studies; specifically, with low blood volume requirements, the characterization of a drug candidate's PK could be performed using a single animal rather than with the current practice of composite PK from multiple animals. Indeed, determining PK from a single animal would most likely provide a better representation of the actual kinetics.

18.4.6 Supported Liquid Extraction

An efficient alternative to traditional liquid–liquid extraction for sample preparation is supported liquid extraction (SLE) offering aqueous sample volumes of up to 400 μL [100,101]. SLE is very efficient, often delivering higher analyte recoveries and cleaner extracts than an equivalent liquid liquid extraction (LLE) method. Moreover, SLE in a 96-well plate format is easily automated with no manual steps such as capping, mixing, centrifugation, and decapping required. SLE plates are most commonly packed with an optimized grade of diatomaceous earth to provide reproducible flow characteristics from well to well.

18.5 A PRACTICAL REVIEW OF THE PRINCIPLES OF CHROMATOGRAPHY

18.5.1 Resolution

The performance of a column can be measured in terms of the height equivalent to a theoretical plate (H), which can be calculated from the column length L and the column efficiency, or theoretical plate number, N :

$$H = \frac{L}{N}$$

The number of theoretical plates is calculated from the equation

$$N = 16 \left(\frac{t_R}{W} \right)^2$$

or

$$N = 5.54 \left(\frac{t_R}{W_{1/2}} \right)^2$$

Figure 18.3 Column efficiency expressed as the number of theoretical plates (N).

where t_R is the analyte's retention time, W is the peak width, and $W_{1/2}$ is the peak width at half height (Fig. 18.3). A lower plate height indicates a more efficient column, and a minimum plate height of about twice the particle diameter is generally expected for an efficient column. The van Deemter equation describes H in terms of its dependence on the linear flow velocity (μ):

$$H = A + \frac{B}{\mu} + C\mu$$

where A , B , and C are the coefficients of eddy diffusion, longitudinal diffusion, and axial diffusion (resistance to mass transfer through and between mobile and stationary phases), respectively (Fig. 18.4). Peak (band) broadening results from an analyte diffusing through a column by following random paths with different lengths. The A term can be related to particle size, how well the column is packed, and the internal diameter of the column. An analyte diffuses from the center of the column out to the

Figure 18.4 van Deemter plot for laminar flow chromatography. The van Deemter curve is a composite of three curves— a (eddy diffusion), b/μ (longitudinal diffusion), and $c\mu$ (axial diffusion, resistance to mass transfer through and between mobile and stationary phases).

edges, and as the velocity of the mobile phase increases, the analyte spends less time on the column, thereby decreasing the effects of longitudinal diffusion. Resistance to mass transfer (axial diffusion) is the partitioning that takes place between the solvent, column packing, and the analyte. If the analyte has a strong affinity for the stationary phase, then the analyte in the mobile phase will move ahead of the analyte in the stationary phase, and the analyte band becomes broadened. In this case, the higher the velocity of the mobile phase, the broader the band.

Chromatographic separation of two analytes, also called *resolution* (R_S), is related to the number of plates in the column, selectivity of the chromatographic system, and the retention of each analyte:

$$R_S = \frac{\sqrt{N}}{4} \left(\frac{\alpha - 1}{\alpha} \right) \left(\frac{k'}{k' + 1} \right) \quad (18.1)$$

where N is peak efficiency, α is the selectivity, and k' is the retention (capacity) factor. To obtain high resolution, the three terms must be maximized. For example, increasing N by lengthening the column leads to an increase in retention time and increased band broadening, which is not desirable for high throughput bioanalysis. The capacity factor might be optimized by changing the column temperature (Section 18.7). Column selectivity is normally optimized by changing the mobile phase composition, column temperature, or stationary phase.

Resolution between two peaks in a chromatogram can be determined by

$$R_S = 2 \left[\frac{(t_R)_A - (t_R)_B}{(W_A - W_B)} \right] \quad (18.2)$$

where, t_R is the retention time of an analyte and W is the Gaussian curve width of the analyte. When resolution is unity, acceptable resolution is achieved, whereas baseline resolution between two peaks requires $R_S \geq 1.5$.

Productivity can be defined as being proportional to resolution per unit time. In other words, it is important to maintain resolution as flow rates are increased; otherwise, no improvement in productivity is realized. The long-term trend toward ever smaller column particle sizes is an effort to achieve the same performance as is possible with larger particles but in a shorter analysis time [102–105].

18.5.2 Optimizing Chromatographic Performance

18.5.2.1 Selectivity. Although increasing resolution by using smaller particles (i.e., increasing N) is a common approach to enabling faster separations, the selectivity term, α , has the greatest effect on resolution. Selectivity is governed predominantly by analyte interactions with both the stationary and mobile phases. Of these, the stationary phase is still the most important consideration for chromatographic resolution. Selectivity differences may be brought about by changes in hydrogen bonding, dipole–dipole interactions, and/or ionic interactions with the stationary phase. Nevertheless, hydrophobic (reverse phase) separations on C_{18} stationary phases remain the most popular choice in most part because of familiarity and availability.

Fortunately, column vendors continue to introduce unique stationary phases that offer the potential for dramatic improvements in selectivity. Examples include biphenyl

stationary phases that show excellent selectivity for aromatic or fused-ring compounds or pentafluorophenyl propyl stationary phases that are very selective and retentive for organohalogens or other compounds containing basic or electronegative functionalities.

18.5.2.2 pH. In reversed-phase chromatography, hydrophobic interactions are the primary mechanism of selectivity between the stationary phase and the analytes of interest. The ionization state of an analyte may alter the degree of interaction with the stationary phase. When a molecule is ionized, it is more likely to participate in hydrogen bonding. In a reversed-phase, aqueous-rich mobile phase, the solute will spend less time participating in hydrophobic interactions with the stationary phase and more time hydrogen bonding in the aqueous portion relative to the neutral species. The result is less retention. When there are significant concentrations of both ionized and neutral forms, the ionized form will have less hydrophobic interaction with the stationary phase while the neutral form will have more hydrophobic interaction. The result is broad or asymmetrical peaks. Moreover, an analyte in its ionized state may participate in unwanted ionic interactions with exposed silanol groups or metal contaminants present in the silica. These ionic interactions may lead to poor peak shape or irreproducibility.

It is possible to predict the ionization state of an analyte relative to the mobile phase pH from the analyte pK_a . The ionization state can then be controlled by simply altering the mobile phase pH. It should be noted that for nonionizable compounds, the retention characteristics remain relatively unchanged throughout the pH range, although the use of different buffers may influence their peak shape.

Partial dissociation of weakly acidic or basic analytes occurs when the pH range of the mobile phase is within two units (above or below) the pK_a of the molecule. Therefore, to avoid unpredictable secondary interactions, the mobile phase pH should be maintained at least two units above (bases) or below (acids) the pK_a of the molecule.

A general observation is that an acidic functionality will tend to have greater retention and efficiency at a pH below its pK_a value and less retention at a pH above its pK_a value. Basic compounds follow the opposite trend; that is, basic functionalities are often less retained at a pH below their pK_a values and demonstrate greater retention and better peak shape at a pH above their pK_a values.

18.5.2.3 Buffer Selection. Next to organic solvent, buffer selection is the most important variable in the development of HPLC method [106]. For example, when separating mixtures containing acids and/or bases by reversed-phase HPLC, it is necessary to control the pH of the mobile phase using an appropriate buffer to achieve reproducible results. Optimum buffering capacity occurs at a pH equal to the pK_a of the buffer. In general, adequate buffering capacity occurs only within ± 1 unit of their buffer's pK_a . Beyond that, buffering capacity will be inadequate. Table 18.1 lists some commonly used buffers for reversed-phase HPLC. Other criteria such as ionic strength, ion-pairing properties, and mass spectrometer compatibility should be considered before selecting any mobile phase modifier. The concentration of the mobile phase buffer usually has little effect on retention in reversed-phase HPLC, provided the buffer concentration is sufficient to control pH; buffer concentrations above 10 mM are usually effective. It should be noted that in situations where ion exchange interactions are occurring between basic analytes and acidic silanols on the surface of silica stationary phases, analyte retention can be affected by buffer concentration. Increasing buffer concentrations may then be used to suppress unwanted ion exchange interactions.

TABLE 18.1 Commonly Used Buffers for Reversed-Phase HPLC

Buffer	p <i>K</i> _a	Buffer Range
Phosphate	2.1	1.1–3.1
	7.2	6.2–8.2
	12.3	11.3–13.3
Formic acid ^a	3.8	2.8–4.8
Acetic acid ^a	4.8	3.8–5.8
Citrate	3.1	2.1–4.1
	4.7	3.7–5.7
	5.4	4.4–6.4
Tris	8.3	7.3–9.3
Triethylamine ^a	11.0	10.0–12.0
Pyrrolidine	11.3	10.3–12.3

^aVolatile buffers suitable for LC-MS/MS.

18.6 EMERGING TECHNOLOGIES

18.6.1 Hybrid Silica Particles

Silica particles possess excellent mechanical strength and efficiencies, but they have a limited range of pH stability. When mobile phases are used with pH < 2, the bonded phase is susceptible to hydrolysis [107], and at pH > 8, particle erosion can occur because of the dissolution of the base silica particle, which can result in a loss of column efficiency, an increase in column back pressure, and bed collapse of the silica packing material [108]. Chromatographic columns based on organic polymers, graphitic carbon, alumina, titania, and zirconia have been demonstrated to have little or no performance degradation when employed with high pH mobile phases (pH 8–14) at elevated temperatures (60–120°C) [109–111]. Unfortunately, the use of these nonsiliceous materials presents their own limitations. For example, organic polymers are generally less mechanically strong and exhibit significantly reduced efficiencies. Graphitic carbon and metal oxides show strong adsorption for many polar compounds resulting in poor peak shapes.

In an effort to maintain the predictable chromatographic performance afforded by silica-based materials, column vendors have turned their attention to the development of hybrid particles that offer high efficiencies and mechanical strength with extended pH stability.

In 1999, Waters launched the XTerra[®] family of HPLC columns featuring a first generation of hybrid particle technology. The hybrid particle was synthesized by replacing one out of every three silanols with a methyl group. The hydrophobicity introduced by the methyl group was distributed through the entire structure of the particle backbone, resulting in a rugged hybrid (inorganic/organic) particle. The presence of 33% fewer residual silanols (after endcapping and bonding) provided higher efficiency chromatography for basic compounds. In 2005, Waters introduced a second-generation hybrid material that utilized an ethylene bridged hybrid (BEH) structure [112]. Compared to the first-generation methyl hybrid particle of XTerra columns, the BEH particle offered vastly improved efficiency, mechanical strength,

and pH range. The BEH hybrid particle is one of the key enablers behind Waters Ultra Performance LC (UPLC™) technology.

Introduced by Phenomenex in 2004, the Gemini product line was the first media to use Two-In-One (TWIN™) technology. Phenomenex used an organosilica grafting process to incorporate highly stabilizing ethane cross-linking. The organic groups are evenly distributed into the grafted layers on the silica surface of a pure silica core. This provides extended pH stability, while maintaining the high efficiency and mechanical strength of a silica particle.

18.6.2 Chiral Columns

Substances that differ only in the spatial arrangement of their atoms are called *stereoisomers*. Certain stereoisomers that differ only in their capacity for rotating the plane of polarized light are termed *optically active* or *chiral*. Optically active isomers are called *enantiomers*. Enantiomers can differ in their potency and selectivity and may exhibit different PK. Indeed, toxicity can be linked to one of the enantiomers [113,114]. Studies of the differences in the pharmacological activities of stereoisomers of a chiral drug are necessary in the drug development process and also required by the regulatory bodies [115].

The separation of chiral drug candidates generally relies on the formation of transient diastereomeric complexes with the stationary phase, resulting in differing chromatographic properties of the enantiomers. Complexes can be formed by hydrogen bonding, ion pairing, metal-ion-to-ligand attraction, π -acid/ π -base interactions, or van der Waals attractions. Resolving enantiomers by forming inclusion complexes with cyclodextrin-based stationary phases is perhaps the most widespread approach in the field [116–118]. Of these, triacetate, tribenzoate, and triphenylcarbamate derivatives of cellulose and amylose derivatives are most common. Several reports, however, have demonstrated the utility of β -cyclodextrin as a chiral mobile phase additive for the separation of enantiomers using reversed-phase HPLC [119–122]. The use of chiral mobile phase additives (CMPAs) provides the flexibility to choose from a variety of achiral stationary phases including sub-2- μ m particles. Indeed, by combining the CMPAs with fused-core particles and ultrahigh performance liquid chromatography (UHPLC) instrumentation, fast/ultrafast enantiomeric separations are possible [123].

Efforts to increase the efficiency of chiral separations have led investigators to utilize supercritical fluid chromatography (SFC) because of the low viscosity, high diffusivity, and low surface tension of the eluent [124–127]. Super- and subcritical carbon dioxide modified with methanol or other solvents easily outperforms normal-phase HPLC because flow rates are typically five times faster with no loss of resolution. Moreover, SFC offers an environmentally friendly alternative to the conventional solvents used in HPLC. It should be noted that some basic compounds and, in particular, amines do not resolve well by using SFC [128]. The effect of the modifier on a chiral separation varies greatly with analyte, but it has been reported that 2-propanol, rather than the more common modified methanol, often leads to better selectivity [129].

Protein-based chiral columns offer an end user the ability to perform chiral separations in a reversed-phase environment where there is applicability to an extremely broad range of chiral compounds, including amines, acids, esters, sulfoxides, amides, and alcohols. Examples of proteins that have been immobilized onto 5- μ m spherical silica particles for chiral chromatography include human serum albumin, α 1-acid

glycoprotein, and the stable enzyme, cellobiohydrolase. The retention and enantioselectivity of these phases can be regulated by changes in pH, buffer concentration, and the nature and concentration of organic modifier.

18.6.3 Monolithic Columns

Modern monoliths emerged between the late 1980s and the mid-1990s to be used as columns for HPLC [130–132]. A monolith is a polymerized porous support structure that fills entirely the column volume without any interparticular voids typical of packed columns [133–135]. Moreover, a monolith is not packed into a column because they are normally prepared *in situ* by polymerization. Monolithic columns have proven to be a very good alternative to particle-packed columns for high efficiency separations in HPLC [136–139]. Because of their small-sized skeletons and wide through pores, these columns provide lower flow resistances and can be operated at high flow rates. Increases in efficiency, however, are moderate because there is greater contribution of a mobile-phase mass-transfer term to band broadening [140]. Also, solvent consumption is considerably higher than that in conventional packed columns and might be an issue for cost-conscious laboratories.

To reduce sample preparation and analysis time, the direct injection of biological samples or diluted supernatant resulting from protein precipitation onto an HPLC column is highly desirable [141,142]. However, the analysis of neat or diluted matrix samples is normally impractical because of the severe buildup of matrix components on HPLC columns made of particulate sorbents. Monolithic columns have proven to be more resilient to this type of approach because of their higher permeability along with the absence of traditional column frits. These differences allow biological matrix components such as proteins to easily pass through the column not affecting column lifetime. Nevertheless, it is always advisable to utilize a higher ratio of dilution in a “dilute and shoot” paradigm to ensure robust LC-MS methods with reduced potential for ionization matrix effects.

18.6.4 Hydrophilic Interaction Chromatography

Reverse-phase LC remains the most widely used technique in HPLC. Molecules are separated based on their hydrophobic interactions between the nonpolar stationary phase and the organic functionalities of typical analytes. However, the retention of polar analytes often requires a highly aqueous mobile phase to achieve retention. Highly aqueous systems sometimes lead to problems such as phase collapse (dewetting) [143,144], decreased MS ionization efficiency because of poor mobile phase desolvation, and yet may still not allow retention of very polar analytes. Some specialized phases were developed to allow the use of highly aqueous systems such as polar embedded phases, hydrophilically endcapped reversed-phase bonded silica, wide-pore low density bonded silica, short-chain phases, and other special designs [143].

Hydrophilic interaction chromatography (HILIC) is a mode of chromatography that can address these issues. HILIC requires mobile phases that are highly volatile (80% organic), are ideal for compound ionization by ESI-MS, and can retain highly polar analytes. The term *hydrophilic interaction chromatography* was first coined by Andrew Alpert to distinguish this technique from normal-phase chromatography [145]. HILIC is run on polar stationary phases such as silica [146–148], amino [149–151], diol

[152], polyhydroxyethylaspartamide, and cyclodextrin-based packing [145,153]. A high organic, low aqueous mobile phase is used to retain analytes with increasing orders of hydrophilicity. According to Alpert, retention is proportional to the polarity of the solute and inversely proportional to the polarity of the mobile phase [145]. On silica columns, the mechanism of HILIC involves various combinations of hydrophilic interaction, ion exchange, and reversed-phase retention by the siloxane on the silica surface [154]. This combination of retention mechanisms results in a unique selectivity that allows for polar retention [154–157].

Conventional SPE methods often contain an elution step that uses a high concentration of an organic solvent. This SPE eluent is not always compatible with reversed-phase analysis. A typical sequence would be to evaporate and then reconstitute into a solvent that more closely matches the initial mobile phase conditions [158]. In HILIC, the high organic eluent is ideal for direct injection, thus eliminating the need for lengthy evaporation and reconstitution steps and increasing throughput [146,154].

18.6.5 Sub-2- μ m Chromatography

18.6.5.1 The Promise of van Deemter. As early as the 1950s, van Deemter realized that peak efficiency could be improved by reducing particle size [159]. Since then, particle technology has continued to advance, whereby column vendors are now able to offer a variety of stationary phases with sub-2 μ m diameters and with the requisite mechanical strength [160–162]. The development of hybrid silica particles was a clear enabler for this technology.

From the resolution equation it can be seen that resolution is proportional to the square root of N . Because N is inversely proportional to particle size, as the column particle size is reduced, resolution increases by the square root of the difference. Similarly, with N being inversely proportional to the square of the peak width, as particle sizes decrease, peak widths become narrower; that is, there is an increase in concentration [163–165]. These improvements, though, come at a cost. Because the pressure required to pump mobile phase through a column is inversely proportional to the square of the particle diameter, the backpressures required for the use of these small-particle columns become quite high [165,166]. Indeed, pressures of up to 4000 bar were used with small-diameter columns packed with sub-2- μ m particles to achieve extraordinary separations [163].

In 2004, Waters Corporation introduced the ACQUITY UPLC that became the first commercially available system capable of pumping mobile phase at pressures up to 15,000 psi. Subsequent introductions of higher pressure capable systems came from Agilent Technologies (1200 RRLC series), Thermo Scientific (Accela 1250), Flux Instruments (Rheos Allegro), PerkinElmer (Flexar™ FX-15), and Dionex (UltiMate™ 3000 RSLC).

An important consideration that limits the use of even smaller particles and higher operating pressures is the occurrence of viscous heating. Viscous heating occurs from the dissipation of the frictional forces when liquid passes through the column bed. The generation of heat results in an increase in mobile phase temperature along the column axis [167,168]. This physical phenomenon produces band spreading, increasing peak width, and produces fronting and tailing. Indeed, the frictional heating of the

mobile phase is thought to be the primary reason for the underperformance of sub-2- μm columns when compared to 3.5- and 5- μm columns [169–172]. Therefore, the use of narrower bore columns with sub-2- μm particles is an important consideration to reduce the impact of radial temperature gradients and maximize chromatographic efficiency.

18.6.5.2 Optimizing Sub-2- μm Chromatography. The goal of any LC analysis is to optimize the resolution between critical pairs of analytes in the shortest time. Unit resolution may be acceptable for many applications, whereas increasing the resolution to 1.5 is considered appropriate for nearly all quantitative analyses. Optimizing selectivity by proper choice of stationary phase and chromatography conditions (e.g., organic modifier, pH, gradient) is far more powerful at improving resolution than increasing separation efficiency with smaller particles. Systematic evaluation of chromatographic conditions can be facilitated by using an automated LC method screening tool.

The transfer of an HPLC assay to UPLC is reasonably straightforward with the following recommendations [173,174]:

- By taking advantage of the high resolution potential of sub-2- μm columns, mobile phase solvent strength can be increased, thereby reducing run times.
- By maintaining optimum mobile phase linear velocities to ensure adequate peak resolution while operating at no more than 80% of the maximum rated pressure of the system. Flow rates are simply scaled in proportion to the difference in column dimensions in order to maintain the same linear velocity.
- Column re-equilibration times can be reduced as a result of low system dwell volumes.
- Injection volume should be appropriately adjusted for the column diameter to achieve good peak shapes. The smaller injection volumes are more than compensated by the increased peak height resulting from the use of sub-2- μm particles.
- By limiting sample volume injections to $\sim 50\%$ of the total loop volume. For systems that utilize air-gap sandwiching of the sample, reducing sample volume allows better utilization of the sample loop and higher injection precision.

18.6.5.3 Linear Velocity. Optimum linear velocity is inversely proportional to particle size, whereas the pressure required to operate at the optimum velocity is inversely proportional to the *cube* of the particle diameter. The pressure limits of the LC pump will therefore restrict the length of column if packed with sub-2- μm particles and operated at optimal flow velocity (~ 0.5 cm/s). Nevertheless, a significant advantage of using sub-2- μm particle columns is the ability to use higher linear velocities without detrimental effects on separation quality. It should be noted that maintaining a separation under gradient conditions when the mobile phase linear velocity is increased requires that the gradient times (t_G) also be adjusted accordingly:

$$t_{G2} = t_{G1} \times \frac{v_2}{v_1} \times \frac{F_1}{F_2} \quad (18.3)$$

where t_G is the gradient time, v is column volume, and F is flow rate.

18.6.6 Pelicular (Fused-Core) Silica

The recent introduction of fused-core silica particle technology has unlocked opportunities for developing higher throughput assays [175–177]. Examples include MAC-MOD Analytical Halo[®] and Phenomenex[®] Kinetex columns. Using sol–gel processing techniques that incorporate nanostructuring technology, a durable, homogeneous porous shell is grown onto a solid silica core. The solid silica cores range in diameters from 1.25 to 1.9 μm and are surrounded by 0.23–0.5 μm superficially porous shells for total particle sizes between 1.7 and 2.7 μm . The highly optimized growth process produces an extremely narrow particle size distribution and dramatically reduces two major sources of peak dispersion, namely, eddy diffusion and resistance to mass transfer. In practice, these fused-core silica particles have shown substantial improvement in chromatographic peak efficiencies over fully porous particles [178–180]. Specifically, the reduction in axial diffusion allows the use of higher flow rates without sacrificing chromatographic performance [181,182]. Compared to sub-2- μm particles, the fused-core particles offer similar efficiency and/or peak capacity at a fraction of the backpressure [183,184]. The adoption of fused-core silica particle technology has been rapid in the pharmaceutical industry for both early discovery [185,186] and late development programs [187].

18.7 ELEVATED COLUMN TEMPERATURES

18.7.1 Theory

Method developers often seek compromise rather than optimization. An often overlooked parameter is temperature that is an easily adjustable parameter and can provide alternative selectivity leading to increased resolution of critical isomer pairs along with an overall reduction in analysis times.

The benefits of using high temperature liquid chromatography (HTLC) were recognized in the 1960s when pioneers such as Giddings and Snyder demonstrated that increasing column temperature could lead to decreased separation times and altered selectivity [188,189]. Recent developments in technology and a better understanding on how temperature can enhance selectivity have created renewed interests in this area [190–192]. As early as 1988, Antia and Horvath [192] proposed in a theoretical study that up to a 100-fold increase in separation efficiency for HPLC can be achieved at significantly elevated column temperatures. A recent publication from Plumb *et al.* described an application utilizing a sub-2- μm HPLC column at elevated temperature to identify metabolites in urine samples. The authors reported a peak capacity of ~ 700 for a 10-min analysis and greater than ~ 1000 in 1 h in gradient elution mode [193]. A number of articles have reviewed the recent advances and applications of HTLC [194–197].

18.7.1.1 Van't Hoff Equation. Increasing temperature alters analyte retention by changing the free energy (enthalpy and entropy) between the analyte and the stationary phase [198,199]. The temperature-dependent free energy changes can be represented using a Van't Hoff plot (i.e., $\ln$ retention factor vs $1/\text{temperature}$). Van't Hoff plots are often linear, and the slope of the line can be used to estimate enthalpy, assuming the analyte retention is governed by only one retention mechanism. Several studies, however, have suggested that changes in temperature affect multiple retention mechanisms,

Figure 18.5 The effect of temperature on resolution. Retention factor of an analyte measured as a function of temperature and represented in a Van't Hoff plot.

including acid–base dissociation rate variations and varying adsorption/desorption kinetics in the stationary phase. The end result is nonlinear Van't Hoff plots, and the phenomenon is particularly evident for ionizable analytes (Fig. 18.5) [200–202].

In general, chromatographic peak efficiency increases as temperature increases, especially at higher flow rates [190]. On the other hand, selectivity can either increase or decrease depending on temperature, and with several other parameters also affecting selectivity (pH, mobile phase, stationary phase, etc.), it is very difficult if not impossible to predict how selectivity will change with temperature. The decrease in linear velocity and increase in the diffusion coefficient with temperature usually results in a decrease in k' (although not always). The decrease in k' would suggest a decrease in resolution with increasing temperature. With the effects of efficiency, selectivity, and retention factor combined, the end result is that resolution generally decreases with increasing temperature [191].

18.7.2 Reality

The conformational changes that occur with long-chain alkyl stationary phases as a function of temperature can produce selectivity differences among analytes. The promise of modulating selectivity by adjusting column temperature is certainly an appealing notion. Shen *et al.* [191] demonstrated enhanced resolution of diastereomers using elevated column temperatures of 100°C and an ion-pairing reagent. As a result of the increased column temperature, the authors achieved a twofold reduction in cycle time and a fivefold improvement in sensitivity.

Still others have employed temperature programming (thermal gradients) as an alternative to solvent composition gradients for the analysis of pharmaceutical compounds [203–206].

Given the difficulty in predicting the effect of temperature on selectivity, it is recommended that chromatography be evaluated over a range of temperatures. Automation

of the process by using chromatographic methods that slowly increment temperature overnight can reduce the overall development time. Concerns regarding analyte thermal stability and irreproducible chromatography because of column thermal instability remain, and they can be alleviated only by controlled investigations.

18.8 ION-PAIR REAGENTS

Volatile ion-pairing reagents such as perfluorinated carboxylic acids are useful because of their compatibility with both LC and MS [207–209]. Perfluorinated carboxylic acids such as trifluoroacetic acid (TFA), heptafluorobutanoic acid, and nonafluoroheptanoic acid have been used with LC-MS and were found to provide similar ion-pair behaviors when compared to the more conventional sodium heptane sulfonate additive. The use of perfluorinated carboxylic acids as ion-pairing reagents to extend the retention time of very polar analytes in reverse-phase chromatography has been reported. In one recent report, Gao *et al.* [209] used perfluorinated carboxylic acids as additives in the reconstitution solution of bioanalytical samples and discovered that the retention times of polar molecules, such as methadone, were significantly extended. The use of perfluorinated carboxylic acids to enhance diastereomer separations has also been reported [191].

Unfortunately, the use of TFA is known to cause ion suppression and must be dealt with if this acid is used in the mobile phase [210]. The use of surface-tension-lowering modifiers to modify the mobile phase and mitigate ion suppression is a common solution [211]. Postcolumn addition of acids and solvent carriers to aid ionization is known as the *TFA Fix* [212].

18.9 MULTIPLEXING LC-MS/MS

Automation of the pipetting and incubation steps of *in vitro* assays makes it possible for a single analyst to generate many more samples in an 8-h period than can be analyzed by current LC-MS/MS systems. Similar improvements in automation of sample extraction have given the analyst the ability to prepare large batches of *in vivo* samples for LC-MS/MS analysis. Once again, the LC-MS/MS interface is the bottleneck and other options are required. It is essential that whatever processes are established that maximize throughput, they must do so without compromising quality.

Parallel or multiplexed LC-MS/MS systems that can analyze the eluent from several LC systems using a single mass spectrometer are one solution to support the high throughput production of quality data.

Waters MUX technology uses indexed LC–MS interfaces from multiple LC systems running in parallel with MS sampling time split between the LC systems [213,214]. The MUX–electrospray interface incorporates either four or eight nebulization-assisted electrospray probe tips arranged radially about the sampling cone. The spray from each tip is successively admitted to the sample cone via a hole in a sampling rotor driven by a programmable stepper motor. The sampling rotor has a supply of heated dry nitrogen to facilitate desolvation of the analyte from the spray selected. An optical encoder on the shaft of the rotating assembly is used to ensure that each mass spectrum is correctly

assigned to the corresponding liquid stream. The inherent duty cycle of this approach, however, limits the MUX system for fast chromatography with multiple components.

The Cohesive Technologies multiplexing system consists of four fully independent HPLC systems fed by two injection syringes on a twin-arm HTS PAL autosampler. Samples are introduced into the atmospheric pressure ionization MS interface via a selection valve. Timing and triggering for injection, gradient start, and data collection are all synchronized by the Aria software. Each system operates independently, permitting multiple methods to run simultaneously, with the MS remaining idle for <4% of the time. With each system operating independently, it is possible to analyze standards, QCs, and study samples on the same hardware. The Aria system uses a modified Twin PAL autosampler from CTC. The two arms and four injectors allow the system to keep up with the required injection speed while maintaining thorough wash cycles for both the syringes and the injectors.

The latest iteration of the system combines the power of on-line extraction with the speed of UHPLC. The Transcend™ system uses Cohesive Technologies' patented TurboFlow® technology with ultrahigh performance capable chromatography systems. The system can alternate between on-line extraction methods and conventional LC methods in a multiplexed manner.

18.10 METABOLITE INTERFERENCES IN QUANTITATIVE ASSAYS

Drugs are xenobiotics to living organisms, which therefore biotransform them to less toxic, less active, and more hydrophilic forms to enhance their excretion. Metabolic pathways are categorized as either phase I or phase II reactions, and both classes of reaction may occur. In phase I reactions, enzymes (e.g., cytochrome P450) modify the parent compound by hydrolysis, oxidation, and/or reduction [215–217]. Phase II reactions conjugate polar groups to the parent or phase I modified compound. Glucuronidation is the main phase II reaction in mammals [218], with other pathways including sulfation, methylation, acetylation, and conjugation with amino acids or glutathione [219,220].

Metabolite identification is central to many of the activities in the discovery and development of drugs. However, quantitative analysis of parent drugs during the early stages of the pipeline often occurs without prior knowledge of the major metabolites of the target analyte. With a requirement for rapid, high throughput bioanalysis, it should not be surprising that a number of methods are developed, wherein the target analyte not only coelutes with endogenous components of biological fluids but may also coelute with biotransformed products of the drug. The presence of unidentified metabolites can lead to inaccurate measurement of the analyte because of ionization suppression, interference in peak integration, or, most problematic, in-source regeneration of the parent drug from phase II metabolites, as the metabolites are not present in the calibration standards and QCs [221]. Common examples of metabolites that undergo in-source regeneration are *N*-oxides [222,223], and both *O*- and *N*-glucuronides [224–227].

The importance of chromatographic separation in quantitative analysis using LC-MS/MS should never be overlooked. Without prior knowledge of the metabolic pathway of a target analyte, it would be best practice to screen a few unknown samples, if available, for metabolites before method validation. The goal of the screening would be to ensure that multiple analytes with similar structures and masses are free of cross

talk [228]. Endogenous isobaric interference from the sample matrix should also be considered [229].

Jemal *et al.* recommended a set of procedures using incurred samples to establish the validity of an LC-MS/MS method for analyzing samples collected from dosed subjects [230]. Specifically, the stability of incurred samples should be investigated before and after sample preparation and SRM (single reaction monitoring) transitions attributable to putative metabolites be scanned using both the same and chromatographically modified LC-MS/MS methods.

18.11 CONCLUSIONS

High throughput bioanalytical methods are essential to support the rapid discovery and development of drugs in the pharmaceutical industry. Nevertheless, the data being produced by these methods needs to be reliable in order to support decision-making processes, that is, the data should be sufficiently accurate and reproducible. Because LC-MS/MS offers high sensitivity and selectivity, rigorous chromatographic resolution and/or tedious sample extraction protocols may not be required; however, appropriate attention still needs to be paid to the quality of the methods to avoid issues with routine sample analysis. A number of sample preparation methodologies have now matured and automation is commonplace. Nevertheless, with chromatographic analysis, times of frequently <3 min, the bottleneck in sample analysis remains with sample preparation.

The importance of sample preparation stems from three major concerns—removing interferences from the biological sample matrices, concentrating analyte(s) of interest, and improving analytical system performance. The choice of sample preparation method should be dependent on the quality of the data required. It makes little sense to invest a month of development time on a method that affords pg/mL sensitivity with accuracy and precision of <15% each for a drug discovery screen that simply requires data that indicates one candidate has better bioavailability than 10 other candidates in a cassette-dosed animal model. On the other hand, it may be important to invest such time to develop and validate a method for a lead drug candidate undergoing human safety assessments when such data is subject to regulatory scrutiny.

The final method should be orthogonal to maximize selectivity and reduce ion suppression. If sample extraction utilized C₁₈ SPE, then the analyst should consider something other than C₁₈ chromatography, for example, a phenyl stationary phase. Alternatively, if strong cation-exchange SPE was selected for sample extraction, any reverse-phase LC method could be utilized. The method should be assessed for recovery, selectivity, precision, accuracy, and ruggedness. Formal validation may yet be required.

19.1 INTRODUCTION

Studies from the late 1980s showed that 40% of the attrition of all drug candidates in clinical trials could be attributed to poor pharmacokinetic (PK) properties [1]. Currently, the primary mechanisms for clinical failure are lack of efficacy and toxicological issues while PK-related failures have been reduced to <10% [2]. This dramatic change

can be attributed to many pharmaceutical companies doing more *in vivo* PK studies and also establishing *in vitro* metabolism groups that were charged to develop and carry out a collection of *in vitro* assays to find compounds with appropriate ADME (absorption, distribution, metabolism, and excretion) properties. To respond to this daunting challenge, high throughput analytical techniques were desired to collect the data. As it turned out, quantitative liquid chromatography–mass spectrometry (LC-MS) fulfilled this need. Moreover, innovations in high throughput quantitative LC-MS have been driven by the ever-increasing need for industrialization of the bioanalytical process within the pharmaceutical industry.

The power of hyphenated chromatography/mass spectrometry techniques, that is, gas chromatography–mass spectrometry (GC-MS), was well established for the analysis of drug compounds and metabolites in the 1980s and into the early 1990s [3]. However, the GC-MS application range was limited to ~15% of the known chemical space since the compounds had to be volatile or made volatile with chemical derivatization [4]. Generally, a GC/MS method that required derivatization requires more extensive method development and sample preparation time than a liquid chromatography–tandem mass spectrometry (LC-MS/MS) method [5]. It had long been known that mass spectrometry (MS) had the potential to supplant other liquid chromatography (LC) detection techniques. The coupling of liquid chromatography with ultraviolet detection (LC-UV) has limited detection sensitivity and was further confounded by specificity constraints, requiring longer run times to obtain sufficient chromatographic resolution. Fluorescence and electrochemical detection offer improvements in specificity and sensitivity of compound detection; these techniques were also coupled with drawbacks, such as the need for derivatization, intrinsic molecular properties, but most often, increased analytical cycle times to ensure analytical reproducibility, particularly in the case of electrochemical detection [6].

Before the advent of API (atmospheric pressure ionization), many other interfaces using various ionization sources were developed to couple LC with MS, including direct liquid introduction [7], moving belt [8,9], particle beam [10,11], thermospray [12,13], and continuous-flow fast atom bombardment (FAB) [14,15]. Intrinsic liabilities and robustness limitations precluded these interfaces from being used for high throughput quantitative analyses. For example, excessive flow splitting from an eluent flow rate of >1 mL/min to the low as 1–10 μ L/min inlet flow rate was required for continuous-flow FAB. Particle beam was more suited for environmental analysis of medium polarity compounds but, in general, exhibited limited sensitivity. Thermospray, a precursor and closely related LC-MS interface to the newer electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) technologies, was the most established and utilized technique for small molecule analysis due to its ability to accommodate higher LC flow rates [12]; however, thermospray was not a truly robust technique. Extended operational use resulted in excessive source fouling, blockages in the thermospray probe, and inconvenient manual intervention, which was not a trivial exercise due to the need for operation within a high vacuum. Thermospray interfaces required extensive tuning; exhibited degradation of thermally labile functional moieties, such as acyl glucuronides; confounding mass assignment; and when compared retrospectively to API, exhibited limited structural coverage.

Publications that outlined the utilization and application of LC-MS dramatically increased through the mid-1990s, primarily because of the invention of second-generation commercial APCI [16,17] and ESI sources [18–20], which could

accommodate higher LC flow rates [21]. Their rapid uptake and acceptance is clearly demonstrated through the explosion of abstracts in the MS community at the 1994 American Society Mass Spectrometry Conference. A total of 413 LC-MS presentations (35% of all presentations) were shown, ~81% featured ESI and ~9% featured APCI. These sources provided a robust, straightforward way to couple LC to a mass spectrometer [21].

In contrast to previous LC-MS interfaces, the API interface enabled facile coupling of LC-MS systems, demonstrated improvements in ionization efficiency, and demonstrated rapid interchange between ESI and APCI probes, as the technique operated outside of the high vacuum region of the mass spectrometer. Contamination from the analysis of minimally purified samples, historically responsible for interface fouling and leading to variance and degradation in mass spectrometer ion transmission performance, could be readily rectified, as the interfaces and ion optics were accessible to the operator for cleaning between runs.

Improved robustness resulted from a number of significant evolutions in interface and inlet (orifice) designs. The original interface technologies employed an on-axis ESI, such as the Branford Analytica and Finnigan MAT first-generation interfaces. The inclusion of a heated capillary ion transfer tube resulted in a degree of gas phase ion declustering and, together with differential pumping systems and multipole ion transmission technologies, provided an analytical footprint for acceptance of LC eluent flow rates of 1 mL/min for APCI and split flow of 200 μ L/min for ESI. The development and commercial launch of ESI interfaces incorporating off-axis [22] and, eventually, orthogonal [23] electrospray emitters relative to the mass spectrometer inlet (orifice), continued to dramatically increase the robustness of API interface. Also, instrument evolution of high purity curtain gas ion optics facilitated higher interface gas loads and eluent flow rates to be used [24]. Incremental improvements in differential pumping, partial pressure ion extraction technologies, interface pumping capacity, and orifice cross section resulted in improved instrument sensitivity. Moreover, these improved API interfaces enabled direct coupling of the LC eluent to the ionization source without flow splitting, reducing postcolumn resolution loss (band-broadening) inherent within early split flow API interfaces [25]. Interfaces could accommodate LC eluent flow rates up to 2 mL/min directly via APCI and up to 1.0 mL/min with pneumatically assisted ESI sources using heated N₂ gas (sometimes referred to as *ionspray*) [22]. It should be noted that the ability of API technologies to predominantly form a single, predictable precursor ion for small molecules, based on ionization mode (positive/negative), has enabled MS operation earlier in the drug discovery process. For example, open-access workflows have been developed to provide additional confidence assignment in chemical synthesis [26]. These features of API, leading to the moniker of “soft” ionization properties, have also enabled automated tuning capabilities for additional efficiency gains.

A striking example of the potential improved throughput using API was demonstrated for renin inhibitor quantitation from human serum using an isocratic LC-MS assay with an APCI source [27]. This assay described analyte peaks 3.4 min after injection, conservative numbers by today’s standards, but may be indicating a degree of empirical experimental design that was ahead of its time in terms of resolution of coextracted matrix constituents, together with the chromatographic resolution needed in selected ion monitoring experiments. More importantly, the method was able to detect and quantify down to levels of 50 pg/mL of the drug, demonstrating the capabilities

necessary to compete with the existing electrochemical and fluorescence detection techniques.

Before the advent of API ion sources, it was known that compound selectivity and thus sensitivity (signal-to-noise ratio, S/N) could be enhanced by performing tandem mass spectrometry (MS/MS) [28,29]. The most commonly used MS/MS experiment in quantitative efforts is the selected reaction monitoring (SRM) scan. The experiment is typically conducted on a triple quadrupole mass spectrometer using the following conditions. The first quadrupole (Q1) transmits a precursor ion (based on mass-to-charge ratio, m/z) of the compound of interest, usually a protonated or deprotonated ion, representative of the original analyte. The second quadrupole (Q2, often called the *collision cell*) is filled with neutral collision gas; a collision energy (accelerating voltage) is applied to induce energy transfer through collision and create a series of product ions through collisional activation of the precursor ion. Lastly, the third quadrupole (Q3) is set to transmit a specific, prominent product ion, before signal amplification. The SRM mode of analysis requires the analyte to transit through two distinct stages of mass-to-charge filtering, thereby increasing analyte specificity, while greatly diminishing the background noise. Performing a SRM scan event, together with an orthogonal separation modality, such as an LC separation, provides three distinct filtering mechanisms to increase specificity in measurement, namely, chromatographic retention time, protonated/deprotonated molecular ion m/z ratio, and product ion m/z ratio. The enhancement in selectivity, sensitivity, and operational utility of the modern triple quadrupole mass spectrometer represents one of the most powerful analytical techniques devised to date.

LC-MS/MS soon became the indisputable gold standard technique for quantitative analysis for *in vitro* and *in vivo* biological samples as is evident by the most commonly performed *in vitro* assays (Table 19.1). The increasing capabilities and utility of LC-MS/MS provided an enabling solution to performing *in vitro* assays on all lead compounds produced in early drug discovery. With this in mind, many researchers in the past two decades began to seek ways to improve quantitative LC-MS/MS throughput. This chapter presents the various methodologies used to obtain high throughput quantitative MS. A series of topics describes specific methodologies that have been demonstrated to directly improve the throughput of the quantitative LC-MS/MS experiment. These topics include automation, MS acquisition method setup, optimization of single and multiplexed LC systems and interfaces into the mass spectrometer, and data reduction. An additional topic covers some new and emerging non-LC-based quantitative MS techniques that show the promise of improving throughput. Although this chapter focuses on *in vitro* assays, many of the techniques described can and have been applied to *in vivo* sample analysis.

19.2 BASIC CONSIDERATIONS FOR HIGH THROUGHPUT LC-MS/MS

To obtain the full advantage of high throughput MS, the entire experimental process requires optimization and understanding of the timelines for each component in the overall process. A question of key consideration is “what is high throughput?” Frankly, the definition of high throughput is somewhat arbitrary; however, the time frames for independent components in the process are germane to defining an approximation to the answer. Perhaps the more telling parameter for high throughput is the cycle time

TABLE 19.1 *In Vitro* Metabolism Assays

Test	Technique(s)	Analyte Monitored	Sample Matrix	Throughput Bottleneck/Comments
CYP inhibition (drug–drug interactions)	LC/MS/MS	Specific probe molecules	Liver microsomes	Number of compounds tested; number of enzymes to be tested; LC run time
	Fluorescence	Fluorogenic probes	Recombinant proteins/buffers	None: relevancy of recombinant protein used, interference from fluorescent compounds
	Luminescence	Luminescent compounds	Recombinant proteins/buffers	Limited types of CYP isoforms
CYP 3A4 induction	Luminescence	PXRE-luciferase	Cells	Highly tuned specific assay
CYP isozyme profiling	LC/MS/MS	Drug and individual metabolites	Recombinant proteins or liver microsomes	Tuning of the mass spectrometer for individual compounds
Caco-2/efflux transport	LC/MS/MS	Drug compound	Buffers	Tuning of the mass spectrometer for individual compounds
PAMPA	96-well plate with UV detection	Drug compound	Buffer	Multiplexed detection, cost-effective—useful in early discovery phase
Metabolic stability	LC/MS/MS	Drug compound	Extract from hepatocytes	Tuning of the mass spectrometer for individual compounds

Abbreviations: PXRE, progesterone X receptor element; PAMPA, parallel artificial membrane permeability assay

for each event. Sample preparation includes off-line or on-line extraction/filtration techniques to reduce sample complexity and novel methodologies to pool samples. Sample preparation has evolved to become generic with/without zwitterionic analog or stable labeled internal standards. Incorporating 96-well plating automation has realized 10 s per sample [30] for preparation schemes, additional parallelization into 384-well plates and above has further reduced these steps to the 2- to 5-s time frame. This at least gives the process a throughput goal for optimization. Sample introduction into the LC-MS system, discounting the influence of carryover, has been realized in the 5- to 10-s time frame, although typically occurs in the 45- to 90-s cycle time frame in which carryover control is desirable, utilizing generic autosampler wash protocols [31–34]. Chromatographic peak widths in the subsecond regime are now readily achievable, utilizing gradient/recycle single-plex LC-MS systems with cycle times of 60 s down to <10 s [35]. Introduction of multiplexing LC systems facilitates eight samples in <60 s, together with incorporation of multianalyte per sample analysis, effectively realizes 1–2 s per analyte in targeted SRM mode and 1–2 s for full scan data [36]. Interfaces can now provide stable response in the 10- to 100-ms time regime; as such, these are now no longer not truly additive to the cycle time. As alluded to above, MS acquisition time frames are in the 1- to 2-s to subsecond regime as a function of the scan events required. It should be noted that the time frames to open and close files has been evaluated as a time-critical variable, and the 1–3 s required for this event have been eradicated from some processes in which a single file is acquired and deconvoluted postanalytically [37]. Lastly, data reduction and posting of data has been somewhat lagging. Functionally, 10 s per sample in review is an appropriate time frame for current workflows. This leaves us with a somewhat realistic argument to the proposed question; it appears that high throughput is 1–2 s per sample, irrespective of the number of independent analytes being assayed.

To achieve these throughput requirements, generic process systems are required. Method development is a key component in targeted assay measurement; however, in high throughput quantitative analysis of multiple chemically diverse compounds, process development is paramount. For quantitative LC-MS/MS, the goal is to produce a separation that resolves the analyte from background components. Unlike LC with a UV detector, the compound can coelute with many compounds because the tandem mass spectrometer will filter out the analyte precursor and product ions away from interfering species via mass discrimination. Generic LC separation, wherein desalting is functionally embedded in the separation, is the common and often only requirement for the LC separation. MS method development includes finding the appropriate precursor and product ion pair transitions for the analyte and maximizing the signal response by adjusting the collision cell pressure and voltage. Data reduction method development includes integration of the chromatographic peaks, assigning calibrators, quality controls, expected concentrations, and acceptability criteria, before posting data to a corporate database.

The key bottleneck for an assay depends on the type of analysis that is being performed (Table 19.1). For example, metabolic stability assays in which 96-well plates filled with unique compounds are analyzed, the critical bottleneck is optimizing the response of the mass spectrometer, that is, selecting the appropriate precursor and product ions and collision conditions for the SRM experiment, with saturation of response mitigated. In contrast, for a P450 inhibition assay in which the same analyte(s) are detected for each sample, the most important throughput constraint is sample analysis

time, predominantly linked to the time of the LC method, requiring development of a short, robust, and generically applicable LC method.

19.3 AUTOMATION OF SAMPLE PREPARATION AND BATCH PROCESSING

Automation of processes is an integral component of the high throughput quantitative ADME workflow, intrinsically linked to the type of *in vitro* assays and projected sample volumes. Detailed process review is necessary to assist infrastructure planning, such as sample tracking, software customization, and amount and types of automated sample preparation equipment, personnel (skill sets and number), and LC-MS/MS systems. Automation of processes requires significant investment capital and long developmental lead times. Ideally, the throughput of sample incubation/preparation should exceed the LC/MS/MS analytical throughput. As the analysis time is reduced, preanalytical systems will be required to provide increased numbers of samples to optimize the usage of the analytical equipment.

In a recent review of automation for *in vitro* analytical laboratories by Saunders [38], key examples of equipment used to automate sample incubation and preparation using sample-plate-based robotic systems were described. The review detailed the extent of automation required for sample volume and types of analyses performed. The type and extent of automation can range from very little (i.e., an autosampler in the LC-MS/MS system), which is well suited for a small start-up company or a university laboratory, to a fully automated system for a larger pharmaceutical or contract service laboratory. Fully automated systems control sample incubations, sample preparation, tuning of the mass spectrometer, automatic transfer of samples to the mass spectrometer, data acquisition, and data processing. These systems are custom built by the company and require extensive internal resources to establish communication and control all the diverse components within the analytical workflow. Examples of fully automated systems have been reported by Janiszewski *et al.* [39] and, more recently, by Laycock [40]. The majority of laboratories fall short of these modular and fully implemented automation solutions. In a typical laboratory, a multiuse multitip liquid handling platform is tasked with dispensing samples, performing off-line extractions, reaction quenching, and dispensing into new plates for subsequent LC-MS/MS analysis. As volume and sample needs increase, these “islands” of automation are readily scaled to match throughput requirements.

19.4 SAMPLE PREPARATION AND POOLING

Numerous and varied ways to perform sample preparation have been described in this volume and are detailed elsewhere (see chapter titled *Direct Biofluid Analysis Systems*) [41]. It cannot be overstated that sample preparation is crucial for the reliability and robustness of the assay using the current LC-MS/MS workflows. The clean-up process not only removes interfering analytes but also enables the filtration of particulates (i.e., microsomes) and reduction of proteins that eventually diminish the performance of the LC separation. Just as the instrumental parts of the analysis need to be optimized for high throughput, so does sample preparation. Off-line procedures such as solid-phase

extraction, sample dilution, and protein precipitation can be multiplexed and allow for plates to be transferred directly for LC-MS/MS analysis [42]. On-line sample clean-up methods have been demonstrated using restricted access media columns and turbulent flow columns and are summarized by Xu *et al.* [41].

Sample pooling is an effective strategy that is employed to improve throughput by reducing the number of analyses conducted. Multiple analytes can be combined [43] and run simultaneously through the biological system (biological cassetting). Smalley *et al.* [44] successfully demonstrated Caco-2 permeability analysis using a biological cassette of 10 samples. The method used on-line solid phase extraction (SPE) LC-MS/MS and achieved a standard curve range of 10–2500 nM with a run time of 3.5 min. Sample pooling involving post dosing sample combination (analytical cassetting) may also be performed after the biological assay is completed [45]. This strategy is generally preferred to eliminate any questions that arise from competition effects (i.e., inhibition) of compounds when presented simultaneously to the enzyme in question. Compounds that can be pooled together typically have different retention times, to minimize the chance of ion suppression effects resulting from coelution with other compounds within the pool.

Another potential approach to reduce the number of analyses, not widely deployed for ADME analyses, is the use of subsetting compounds based on chemical properties. Using *in silico* methods, specified compounds with diverse chemical motifs are selected for potency screening from a limited number of well plates. Statistical models are used to predict compounds that have similar chemical properties to the training set hits, to “cherry pick” from the compound collection for additional screening [46]. The authors noted that the results from the subsetting approach compared favorably with data obtained from a traditional screening approach and led to a reduced sample analysis burden of ~75%.

Another pooling approach is to determine the effect the compound has on multiple enzymes in a single analysis using a cocktail of probe substrates. This workflow was demonstrated by Kim *et al.* [47] for the analysis of inhibitory potential of nine CYPs by measuring the metabolized products formed from microsome incubations containing six- and three-probe compounds, respectively. The incubations were pooled together before analysis. The LC/MS/MS run time was 6.5 min for each pooled sample. The methodology provided only a modest improvement in analytical throughput because of the slow LC analysis conditions when compared to what can be achieved using the RapidFire™ (see below). However, this assay did effectively increase the coverage of CYP enzymes studied and somewhat minimized material usage.

19.5 MASS SPECTROMETRY METHOD DEVELOPMENT—TUNING AND CHOICE OF MASS ANALYZER

For experiments that perform a single or a limited number of samples for each analyte (i.e., metabolic stability, Caco-2), mass spectrometer method development becomes a critical factor in throughput enhancement. Practically, sample is infused or loop injected into the mass spectrometer for selection of precursor and product ions to be monitored on a triple quadrupole instrument. Additionally, interface gas flows, polarity, and ion optics setting are tuned to optimize transmission of the precursor ion. Subsequently, the collision cell accelerating voltage is adjusted to identify the most prominent product ion, before fine-tuning of collision cell conditions to optimize

the response of the SRM transition. Computer-driven programs have been developed to automatically perform this task [37,48–52]. These programs perform a series of multiple loop injection experiments to optimize these previously described variables and can significantly reduce the development time requirements. Success with these technologies does come at a price. When loop injection is performed, the signal profile changes quickly (i.e., peaks can become as narrow as or narrower than a LC peak), thus the analyte signal is changing very quickly as a function of time. This can result in limited time for algorithms to find optimal settings for each parameter. Reduction in the flow rate to allow increased residence time of the flow injected analyte bolus is often used to extend the amount of time a steady signal is delivered to the instrument. This process overcomes constraints within the selection of SRM transitions; however, tuning of the ion source parameters may be compromised since optimization of some of ion source voltages can be dependent on eluent flow rate. Ideally, obtaining a steady flow of sample at the same flow rate used for the chromatography method is required. Conversely, performing these procedures manually consumes a significant amount of time (4–10 min per sample); thus, a 96-well plate with eight discrete analytes would require 32–80 min to complete tuning of the instrument. Moreover, choosing the appropriate analyte(s) serving as tuning compound is critical since carryover issues can occur, which for sticky compounds could require extensive time (hours) to flush the compound out of the instrumentation setup. In many cases, instrument tuning time is greater than the overall analytical time frame for quantitative LC-MS/MS analysis of the samples themselves.

Alternate approaches to relieve this bottleneck have been described by Kieltyka *et al.* [53] utilizing an autosampler to infuse samples into the MS system. Besides delivering sample to the source, the system using QuickQuan 2.0 was able to tune the mass spectrometer at a rate of 2.5 min per analyte. For a plate consisting of 48 discrete compounds, tuning was completed within just <2 h. These investigators reported that using this tuning procedure and a dual chromatography system for analysis, they were able to obtain a throughput of 1300 compound assays with 500 discrete compounds per instrument per month with a 95% success rate. Figure 19.1 summarizes the informatics workflow for this automated tuning process.

In larger laboratories with common vendor-supplied triple quadrupole mass spectrometers, databases have been developed to store and recall analyte tuning parameter files, reducing the time requirements for subsequent method development for the same analyte [40]. The realization of this protocol owes much to the reproducibility of MS systems manufacturing. For successful implementation, instruments using shared tuning parameters must meet a specific performance requirement, using a standard compound analyzed using fixed ionization source and collision cell conditions, to ensure that each instrument is performing optimally.

A strategy to avoid optimizing the SRM transition is to use another type of mass analyzer. For example, a single quadrupole in full scan [54] or single ion monitoring mode [55] has been utilized for quantitative ADME experiments. As discussed previously, this leads to compromised selectivity, decreased sensitivity, and concordantly, increased sample consumption. Ion trap mass spectrometers have also been utilized, whereby the ion trap is operated in product ion MS/MS mode. Quantitation is established by extracting the analyte-specific product ion(s) produced from a given precursor ion and is performed during postacquisition analysis from the total ion chromatogram. Typically, the mass window for these mass chromatograms is approximately ± 0.5 Da

Figure 19.1 The integrated informatics workflow employed by Kieltyka *et al.* [53]. A customized software tool, STARscreen, provides corporate gate-keeping function and tasking lists for QuickQuan 2.0, including all relevant import list details and final data release/upload. The automated analyte MS optimization process is executed via QuickQuan 2.0 using infusion syringe driven optimization, allowing appropriate time to generate high quality MS acquisition methods. Batch import and process method assignment is controlled automatically through QuickQuan 2.0, including user-specified generic methods. Staggered dual-column analysis is executed for accelerated throughput, of particular note in the process; the import list generated by STARscreen incorporates the analytical staggering process automatically, using alternating samples from two discreet plates. Manual data review and data release processes follow initial autointegration.

wide, a function of the unit mass operation of the ion traps used. A key efficiency advantage to this approach is the use of “universal” collision conditions, circumventing tuning for specific SRM transitions [56]. Typically, this platform is 10 times less sensitive than the current triple quadrupole MS-based platform [53].

Another application involves the use of an orthogonal acceleration time-of-flight (TOF) mass spectrometer [57,58]. The TOF detects all ions within a given mass range (i.e., it cannot be fixed to monitor for a specific mass) and can be more selective than the quadrupole based on its higher mass resolution capability. Moreover, current TOF mass analyzers have a very fast duty cycle—20 Hz or faster, which improves its detection capabilities for sampling subsecond wide chromatographic peaks that elute in an ultrahigh performance liquid chromatography (UHPLC) separation. Initial experiments performed with a TOF with a resolving power of 5000 showed ~5–25 times less sensitivity when compared to the triple quadrupole together with limited dynamic range [57]. Using narrow mass width extracted ion chromatograms of 0.1 Da for quantitation, linearity and sensitivity (signal-to-noise ratio) approached that produced by a triple quadrupole system. However, at this resolving power, chemical noise is not always fully resolved from the analyte, so higher resolving power would be of further utility. There is growing interest in revisiting the TOF experiment now that TOF/Q-TOF (quadrupole–time-of-flight) instruments with resolving powers exceeding 20,000 and better sensitivity are commercially available. These technologies permit the use of even narrower mass width ion-extraction chromatograms (0.01–0.005 Da), to produce an extracted ion mass chromatogram for the molecular ion with minimal contributions from chemical noise. Since data are acquired over a wide mass range without *a priori* mass spectrometer tuning, acquired data can be processed to find masses of expected analytes and metabolites, especially when accurate mass measurements are performed [59]. This approach has been termed as *quantitative/qualitative (Quan/Qual) workflow* [60] and has been applied routinely for metabolic stability assays. Moreover, when a Q-TOF instrument is utilized, data-dependent MS/MS experiments can be triggered to provide additional structural information [58]. Even higher resolving powers 100,000 full width at half maximum (FWHM) in a 1-s scan cycle can be achieved using the Exactive™, a benchtop orbitrap mass spectrometer [61]. Reports have shown this system supporting metabolic Quan/Qual stability experiments [60].

19.6 LC METHOD CONSIDERATIONS

The orthogonal nature of LC-MS/MS and relative differences in cycle times between these techniques has realized the greatest diversity and efforts in enhancement of throughput. The mass spectrometer, when set in SRM mode, is capable of detecting analyte response every 10–100 ms, whereas the LC system typically requires minutes to deliver the sample to the mass spectrometer. Thus, sample analysis throughput improvements are primarily dependent on optimized sample delivery to the mass spectrometer. This can be accomplished by reducing LC separation time or multiplexing (multiple LC separations to a single MS system) to align the throughput scales of the systems. The main function of the LC separation in a SRM experiment is to separate analyte from species that cause ion suppression, such as nonvolatile salts, proteins, or phospholipids.

In early experiments, isocratic high performance liquid chromatography (HPLC) methods were common and achieved run times of <3 min per injection [6,27]. However, isocratic methods require redevelopment of the LC method conditions each time a different analyte is selected for analysis. Moreover, isocratic methods suffer from column contamination from retained lipids and proteins.

A more practical approach involves the inclusion of a binary gradient HPLC method, the goal being to provide appropriate LC separation quality across the majority of chemical space, without individual analyte reoptimization, minimizing ion suppression, and column contamination. An important consideration to achieve high throughput LC separations is reduction of system volume for gradient mixing experiments. System volume is composed of a delay volume in pumping systems, solvent mixing, extra-column tubing, LC column volume (at least 60% of the LC column volume unpacked), and postcolumn interface volume. Pump dead volume results in a gradient delivery delay to the column and also lengthens column reequilibration time. Manufacturers have reduced extra-column volume significantly with the development of UHPLC systems. Improvements in column packing materials have resulted in reduced variability from residual silanol activity. Better reproducibility of silica particle cross section has resulted in a reduction in tortuosity, the A term in the van Deemter equation. Manufacturing processes have also improved column packing reproducibility. Finally, gradient separations result in chromatographic peaks with reduced peak tailing, leading to improved detection limits.

A generic gradient LC separation will include a 3- to 5- μm , C18-functionalized silica particle packed into a column of dimension 2.1 mm in diameter by 30–50 mm in length. Flow rates are typically delivered in the 0.5–1.0 mL/min range. Generic reverse-phase linear gradient separations start at a low organic concentration, typically, acetonitrile at 0–5%, 95–100% aqueous 1 mM ammonium formate, and 0.1% formic acid, and elute at a sufficient organic concentration to remove proteins and some lipids (95–100% acetonitrile). The solvent flow rate and slope (gradient time), along with the stationary phase of the column, are principle drivers in determining the speed of the LC-MS/MS analysis and the chromatographic resolution achieved. Generic LC conditions become more tailored and refined if insufficient compound detection occurs or if the compound will be continuously analyzed for many studies. During process refinement, different variations of C18 columns or stationary phases (i.e., C8, cyano, phenylhexyl, etc.) may be investigated to obtain increased throughput and improved selectivity.

Recent advances in LC column technologies have resulted in further choices for high throughput LC-MS. Good results have been demonstrated with the use of monolithic columns [62,63], where the intrinsic porosity ($\sim 15\%$ > standard columns) provides for separations at significantly higher flow rates (up to 5 mL/min). With preinterface solvent flow splitting, chromatographic separation of bupropion and its metabolites was achieved in 23 s [64]. Similarly, fused-core columns have become available that provide higher resolution separations than conventional spherical semiporous 3- μm particles, with reduced separation timescales. Fused-core LC columns enable higher flow rates (>1 mL/min) without producing a pressure drop that exceeds the 400-b pressure limits of standard HPLC systems. These benefits do come at a price. Gradient reconditioning before the next assay is required, which is essentially dead time in an assay. Alterations in the workflow, such as multiplexed LC analysis (see below), are necessary for realization of the true chromatographic efficiency gains.

The evolution of UHPLC has provided an alternate methodology to accelerate LC cycle time [65]. With UHPLC, better chromatographic separations can be achieved in a shorter timescale than that with conventional HPLC columns, since columns with smaller (sub-2 μm) particle size particles realize improved theoretical plate heights at the same linear velocity, when compared to columns with 3- to 5- μm particle sized particles. Moreover, UHPLC pumping systems have been designed with reduced system volume ($\sim 60\ \mu\text{L}$) and higher operating pressure regimens, up to 1800 b. Cycle time reductions of two- to threefold have been demonstrated by multiple laboratories [66–68], with a concomitant increase in sensitivity through chromatographic peak compression.

Sample throughput is impaired by autosampler cycle time constraints. For a highly optimized LC method ($<60\ \text{s}$), a significant portion of the injection-to-injection cycle time is invested in a number of autosampler tasks. Typically, the autosampler receives a signal from either the mass spectrometer or the data system that the previous analysis is complete and starts a cycle. The autosampler aspirates the next sample in the queue, transports the sample or an injection needle to enable injection, and injects the sample. Following injection, the autosampler is tasked with preparing the system for the subsequent injection (i.e., washing the sampling valve). As LC throughput increases, the cycle time of the autosampler becomes the dominant factor in efficiency enhancement as preinjection delays of up to 20 s can occur. Technologies such as “inject ahead” have been developed to reduce this problem [69]. Inject ahead enables the autosampler to wash the injection device and inject the next sample during the analysis of the previous sample.

19.7 HIGHER THROUGHPUT SERIAL LC-MS/MS

Solid-phase extraction provides less chromatographic resolution than that of LC; however, sufficient resolution can be obtained to desalt the analyte and reduce the levels of proteins, salts, and detergents that can suppress the analyte response in a rapid timescale MS analysis. Inman *et al.* [70] described an off-line SPE method that enabled 24 s per sample MS analysis times for metabolic stability samples. The method used SPE cards in a 96-well plate format. Samples were processed using a SPEExpress system, composed of a Harvex liquid handler with an array of 96 needles, and transferred into the SPE elution zones on the card-containing Empore C18 media. After that, the analytes were washed with aqueous mobile phase to remove buffer salts. The sample plates were transferred into the Elutrix unit and eluted from the SPE resin into the mass spectrometer with a C18 guard column coupled in between to enhance peak shape. The Elutrix unit had the capacity to hold 35×96 -well plates for unattended analyses. Good correlation between traditional LC-MS/MS and SPE-MS (solid-phase extraction–mass spectrometry) were observed ($R^2 > 0.92$) for *in vitro* clearance samples from human and dog microsomes. This chapter described the impact of limited chromatographic resolution and reduced recoveries for highly polar analytes, which affected the results obtained by the SPE method.

An innovative on-line SPE instrument, RapidFire, has been introduced by Biocius (formerly BioTrove). Originally designed as system for high throughput biochemical screening [71,72], the system has recently been applied to *in vitro* screening of CYP inhibition [73], Caco-2 (Özbal 2009, (Fig. 19.2) Personal communication), and

metabolic stability [74] assays. The RapidFire system utilizes three isocratic pumps to deliver a low organic strength mobile phase and two eluents with high organic strength mobile phases delivered at flow rates of 1–1.5 mL/min. Columns similar to those described by Janiszewski *et al.* [51] but with smaller bed volumes are utilized. The system consists of four valves (three high speed–low dead volume switching valves and a four-port valve), an injection needle that utilizes vacuum aspiration of the sample to an injection loop, a set of wash stations, a three-dimensional translatable well plate stage, and a well plate stacker. An injection cycle consists of three distinct steps: load, desalt, and analysis. The valve timings are set so that a single sample can be analyzed every 6–10 s. Recent CYP450 inhibition assay studies screened for inhibition of 1A2, 2C8, 2C9, 2C19, 2D6, and 3A4 isoforms [73]. Good correlation was obtained for data acquired on pooled samples analyzed by RapidFire, MS/MS and a 2-min LC-MS/MS method. Lim *et al.* [73] reported that a 96-well plate was analyzed in 15 min by the RapidFire method, while the LC-MS/MS method required 4 h. A drawback of the reported data was significant carryover, between 1% and 4.1%.

Multiple column functionalities are available for highly polar compound extraction (hydrophobic interaction liquid chromatography (HILIC) extraction media), overcoming a number of the analytical constraints observed by Inman. When coupled with quadrupole TOF system, it is plausible to obtain both quantitative and qualitative information on consecutive injections of the same sample through postacquisition data mining.

19.8 MULTIPLEXED SYSTEMS

Currently, the most efficient LC-MS systems have maximized MS data collection rate and minimized the time spent detecting noise. These designs have moved away from the serially delivered single LC-MS/MS platform, requiring sacrifices in LC resolving power, while retaining the inherent lag time of LC reconditioning and autosampler processes. When a single analyte is being analyzed in a very fast UHPLC run, the peak width is approximately one-thirtieth (2 s wide/60 s gradient) the time of the separation. Many techniques have been devised to increase the number of analyte signals detected during a single MS acquisition. Multiplexing the number of chromatography columns attached to a single mass spectrometer is a commonly used option. There are three major families of multiplexed experiments: staggered parallel dual-column analysis with off-line column regeneration, true parallel chromatographic separations (MUX), and staggered parallel.

Figure 19.2 (a) An example of data generated using the RapidFire system for metabolic liability analysis, as describe by Luippold *et al.* [74]. Single data files are acquired, following similar preanalytical principles as described in Fig. 19.1, with 8 s per sample acquisition rates. Analyte (top) and internal standard (bottom) are automatically integrated using QuicCalc, area responses are displayed in a tabular format on for rapid data review and release. Of particular note, the process assays the latest time points first (likely the lowest concentration) to minimize errors associated with carryover effects in quantitation. (b) Studies comparing the RIAS (rapid and integrated analysis system, utilizing the RapidFire) and a validated LC-MS/MS assay (10-fold lower throughput). Reference compounds were assayed in duplicate across three separate days using both processes; calculated half-lives ($t_{1/2}$) between platforms indicate excellent correlation. (See color insert.)

19.9 STAGGERED PARALLEL DUAL COLUMN WITH COLUMN RECONDITIONING

A simple method to overcome the gradient reconditioning time involves a dual-column analytical separation with a secondary pump for off-line column reconditioning. The analytical setup is composed of two 6-port valves, a gradient mixing LC pump, and an isocratic or gradient conditioning pump. This setup enables parallel processing of LC columns to be effected. When an analytical separation is being delivered to the mass spectrometer from the gradient LC pump, the second column undergoes reconditioning with the starting conditions for the gradient separation, isocratically delivered by a secondary LC pump. Subsequently, valve switching occurs to index the reconditioned column in-line to the autosampler and detector for the next assay while reconditioning the previously used LC column. Enhancements such as inject ahead autosampler operation may be employed to further improve throughput. The dual column configuration has been successfully deployed to support a variety of *in vitro* assays.

An example of this analytical setup was described by Janiszewsk *et al.* [51], using an OptiLynx 1 mm $\times$ 15 mm, 40- μ m pellicular pore C18 columns. The system consisted of a dual-arm autosampler with a dual chromatography system to provide column cycling and peak stacking. Two isocratic pumps delivered low and high organic strength mobile phase to the columns, which were set on opposing arms of a 10-port switching valve. The system timing delivered high organic strength mobile phase 18 s after injection onto column 1 to elute the analytes to the mass spectrometer. At 24 s after injection, aqueous flow was diverted through the autosampler and the second sample was injected onto the second column. During this time, the first injection needle was washed before subsequent injections and the process was repeated. The system was utilized for a variety of ADME studies including metabolic stability and Caco-2 assays and was reported to have a capacity to run over 2000 samples per instrument per day (Fig. 19.3).

19.10 MULTICOLUMN PARALLEL CHROMATOGRAPHY—SINGLE IONIZATION SOURCE

Xu *et al.* [55] demonstrated the utility of an eight-way “true” parallel LC-MS system for the analysis of metabolic stability samples. The system consisted of an LC pump, Gilson 215 eight-tip autosampler, an AB/MDS-Sciex API 165 mass spectrometer, two Valco valve manifolds, eight 10 mm $\times$ 1 mm i.d., 3- μ m particle sized HQC18 PEEK microbore columns, and a Valco switching valve to divert the solvent front to waste.

Figure 19.3 (a) The dual-column high capacity LC-MS configuration, as described by Janiszewski *et al.* [51]. The system schematic indicates the positioning of custom dual injection system and the 17-plate deck of the Gilson 215 multiprobe autosampler, together with in-line selector valves for dual-column/dual-pump operation, all operated under computer and pump signal control. (b) The specific valving configurations for the aqueous solvent flow (sample collection from the dual injection loops, LC column reconditioning, and gradient starting conditions). (c) The valve orientation to provide sample loading and subsequent elution to the mass spectrometer for dual-column analysis.

Using an accelerated (ballistic) gradient separation, of ~ 0.8 min per cycle, the system was capable of running 240 samples per hour. To enable analyte focusing during injection, sample preparation utilized trichloroacetic acid instead of acetonitrile. The group reported that on average, 65–70% of samples were successfully analyzed by the system. Three major reasons for failure included poor compound solubility, weak ion signal, or experimental pipetting/injection errors.

19.11 MULTIPLE COLUMN PARALLEL CHROMATOGRAPHY WITH MULTIPLE ESI SOURCES

A variety of multiple electrospray systems have been studied for many different MS applications [75–78] and were later investigated for the use in quantitative efforts [79–81]. Multiple spray sources can be termed as *nonindexed* or *indexed spray sources*. For nonindexed spray sources, spray is continually sampled by the mass spectrometer from all sources. Indexed sources enable only one channel to be sampled by the mass spectrometer at a time. For quantitative efforts, nonisobaric species must be analyzed from each channel (e.g., mass spectrometrically distinct compounds) when a nonindexed source is utilized.

A simple dual-spray system was described by Hiller *et al.* [81] using a Sciex 3000 triple quadrupole MS system. A Turbospray source with two electrospray and heater units was developed. The dual sprayers were coupled to two separate LC systems each of which had column regeneration capabilities. The autosamplers were synchronized to simultaneously inject sample so that data could be recorded in a single data file to generate a cycle time per compound of 30 s. Utilization of the dual-probe approach generated a twofold improvement in throughput with data quality that was deemed adequate by the authors for discovery-based quantitative applications.

The most widely used multiple sprayer source was the multiplexed electrospray interface, MUX, introduced by Waters in 1999 [75]. The device consists of API interface that composed of either four or eight sprayers. A rotating valve with a machined slot is located between the fixed electrospray probe tips and the skimmer cone of the instrument. The rotating valve serially selects an electrospray probe to sample for a finite period (50–200 ms), while excluding the majority of eluent sampling from the other electrospray emitters. The rotating valve indexes to the next sprayer (50 ms) and so forth to realize a sampling duty cycle of 400–1000 ms for a four-channel system and 800–2000 ms for an eight-channel system. The rotating valve was designed to reduce the gas load on the vacuum system at the interface and eliminate any ion suppression effects caused by the other sprayers. Independent LC columns were connected to each sprayer tip and solvent delivery was provided by either a single LC pump, split across all columns and sprayers, or column-/sprayer-independent LC pumps. Data for each column were encoded into individual channels and into a single data file. With such a system, the same or different analytes could be analyzed on all channels.

Morrison *et al.* [82] and others have demonstrated that the system does suffer from reduced sensitivity related to the duty cycle constraints. Lower flow rates or flow splitting was required for optimal performance to further reduce the load of liquid introduced to the API region. Cross talk between spray channels have also been a body of concern with this method, although selection of the appropriate assay type and

sampling strategy negated this bias [82], as was demonstrated by Fung *et al.* [49] in utilizing the MUX interface to multiplex their Caco-2 permeability assay.

The dual-channel MUX interface is more commonly implemented now and has been successfully employed on TOF and Q-TOF instruments to enable the introduction of reference masses to obtain accurate mass measurements [77,78]. Utilization of a lock mass enables on-the-fly correction of the mass-scale and improves mass axis stability. When coupled with higher resolution measurements, improved mass axis stability enables the use of narrower mass widths (i.e., increased specificity) when extracting the signal for an analyte from the mass chromatogram, leading to improved sensitivity and specificity.

An alternative dual- or four-spray-indexed interface was described by Schneider *et al.* [80] In this interface, an electrospray probe was paired with an ion lens located near the tip of the probe. A voltage was applied to synchronously enable or disable the spray from reaching the entrance lens to the mass spectrometer. The signal emitted from a probe could be fully turned-off or -on rapidly, within 50 ms of the change in the lens voltage.

In terms of throughput, multiple sprayers increase throughput as a function of the number of sprayers introduced into the system. After their initial introduction, these systems have lost favor because of the reduction in sensitivity and increased complexity in terms of MS hardware when compared to other multiplexed systems.

19.12 STAGGERED PARALLEL CHROMATOGRAPHY

The use of staggered parallel technologies has ameliorated a number of the issues associated with the parallel systems described above. The concept of staggered parallel chromatography is shown schematically in Fig 19.4. Sample is injected onto column 1, using an independent LC pump, and most often, acquired to an independent data file. After a fixed time (Δt_{inj}), another sample is injected onto column 2. The same steps are repeated for columns 3 and 4 in a four-channel multiplexing system. Before elution of analytes from column 1, eluent streams (analytes) are delivered into the mass spectrometer by means of a selector valve. Following a predefined acquisition window, column 1 eluent is diverted to waste and column 2 is selected for elution to the mass spectrometer. The same steps are repeated for columns 3 and 4, and the cycle repeats again. The advantage of such a system is that it enables multiple columns to be coupled to a mass spectrometer fitted with a conventional ESI/APCI source for class-specific analysis. The staggered parallel strategy maximizes the time spent by the mass spectrometer detecting analytes, which elute in 3- to 10-s peak widths and minimizes the time spent detecting background and chemical noise. With a minimal increase in run time compared to a single LC system, over a threefold improvement in sample throughput is typically achieved.

The concept was originally described by Van Pelt *et al.* [83] using a single LC with pressure regulation to control the flow to the individual columns and calibrated loops to delay to the delivery of mobile phase to the columns. The concept was refined by using three [84] or four [85] columns with multiple LC pumps and a multiport autosampler for *in vitro* Caco-2 screens. With the four-column system, it was reported that 600 samples could be analyzed during an overnight period (~16 h). These technologies have now been commercialized into a dual-CTC arm,

Figure 19.4 (a) The four- or eight-channel LC-MS configuration, as commercialized by Thermo Fisher. The system schematic indicates eight LC pump systems, facilitating either four-channel operation with column switching or eight-channel operation as single dimension LC separations. A dual-arm CTC autosampler with two- to eight-injection valves provides sample aspiration and injection. Dual-switching valves (A/B) enable column switching selection for analysis and a selection valve gates the appropriate LC eluent stream to the triple quadrupole mass spectrometer (QQQ). (b) Sample delivery is staggered in time such that the appropriate eluent stream windows (shaded and numbered) are serially selected for MS detection with an interacquisition delay for independent acquisition file open/closure events. (See color insert.)

two- to eight-pump, and one- to eight-channel staggered parallel system, as shown in Fig. 19.4. Where the same assay is run across multiple channels, there has been concern raised to intercolumn retention time variability. Variability can be reduced by purchasing columns with the same lot of packing material. Briem *et al.* [85] reported that 2000 injections could be made on the columns without notable increase in backpressure or change in chromatographic properties.

19.13 INFORMATICS

As the number of data points generated increases, so does the burden on data processing and reporting. This requires increased efficiency and robustness in the procedures used in method development (discussed above), sample tracking, data analysis, data processing, and posting, and reviewing [39].

Data processing mainly consists of peak integration, generation of calibration functions from fitting standards, and converting sample signal response into a representative concentration and has almost exclusively been developed inside each company by customizing vendor-provided software with the use of visual basic scripting. Most MS vendors have fully automated peak integration routines. However, automated procedures can fail to pick non-Gaussian peaks, especially those at low S/N ratios. These results require manual review and integration, which for large data sets is very time consuming. For single-shot data, the data can be directly posted into the corporate database for the compound tested. For dosing experiments, response curves are plotted and fitted to find the IC_{50} values, which are subsequently reported to the database. Finally, after data posting is completed, the data are reviewed to determine what compounds have favorable or unfavorable *in vitro* ADME properties. Using defined search criteria, the results can be automatically filtered to provide this information. An excellent example of the interconnectivity and rational design of automation, auto-tuning, multiplexed measurement, library searching and final results posting was recently shown by Laycock [40]. Proprietary data processing systems have been developed and described, accommodating many of the principles described so far, namely, single data file acquisition and rapid manual data review processes, to achieve manual data review and release of 96-well plate data in 5 min [86]. Ascent™ is a commercial solution to instrument-independent peak processing and automatic data release, which has been developed by Indigo Biosystems. Software algorithms provide a numerous array of chromatographic, analytical troubleshooting, and quality scoring solutions to remove the majority of manual peak review. While these technologies have been predominantly employed within the high throughput clinical diagnostic laboratory, the analytical efficiency needs are similar, and it is anticipated that the quantitative *in vitro* setting will embrace this approach [87,88].

19.14 NON-LC-BASED HIGH THROUGHPUT MASS SPECTROMETRY

A continual theme in the previous sections involved efficiency gains through the sampling capabilities of LC-MS/MS. This has been predominantly achieved by sample pooling, reducing the autosampler and LC cycle times, or multiplexing the number of LC systems connected to the mass spectrometer. An alternate approach is to eradicate the LC dimension entirely. The gains would be simplification of the equipment burden and removal of the cycle time limitation imposed by the autosampler/LC hardware. The obvious concerns are reliability, reproducibility, and robustness of these approaches, particularly in light of the inherent reduction in matrix effects observed when an appropriate LC separation is utilized. *In vitro* ADME samples are less complex than plasma-based samples and may be more amenable to such approaches. A newer suite of technologies have been proposed, including MALDI or the recently introduced ambient ionization techniques including desorption electrospray ionization (DESI), direct analysis in real-time (DART), or laser diode thermal desorption–atmospheric pressure chemical ionization (LDTD-APCI). Each of these techniques proposes the potential for no or minimal up-front sample preparation before analysis and depends on product ion MS/MS or single ion reaction monitoring to provide an effective method filtering out the response of contaminant species.

19.15 LASER-BASED IONIZATION METHODS

One alternative that was commercialized under the product name FlashQuant consisted of a MALDI ionization source coupled to a triple quadrupole instrument (MALDI-QQQ) [89–92]. Samples were spotted onto MALDI target plates with matrix and were analyzed by rastering the MALDI plate through the laser beam. The fastest sample analysis rates ever reported were achieved by this equipment at 1.2 s per sample (Fig. 19.5) to enable analysis from 384 wells in <7.7 min [93].

Since a triple quadrupole was utilized, SRM transitions were used to provide compound specificity and removed the difficulties of detecting small molecules in the presence of interfering ions. This technique did not resolve ion suppression effects

Figure 19.5 (a)MALDI-QQQ readout of the substrate acetylcholinesterase (light gray) and enzyme product, choline (black) used to probe AChE inhibitors as described by Rathore *et al.* [93]. Rastering rate of the laser beam was set at 9 mm/s, identical to the spot width of a 384-well plate, realizing a sampling rate of 1.2 s per sample, accounting for plate stage movement. Reproducibility (%RSD) of measurement of substrate and product was <12%. (b) Ten-point concentration-dependant inhibition assays for AChE against known inhibitors, results are plotted from triplicate analysis with mean and $\pm$ standard deviations shown.

from the presence of salts, proteins, and other molecules, which will generally reduce sensitivity. For less complex biochemical systems, no sample clean-up was typically required [93]. However, for more complex sample mixtures such as microsomes or plasma, an off-line liquid–liquid extraction or SPE clean-up step was typically required, limiting the overall process sample throughput. The effect of ionization suppression effects was illustrated by Kovarik *et al.* [92]. Using protein precipitation of plasma and 4 times washing *in situ* on the MALDI plate, acceptable accuracy and sensitivity of 1 ng/mL was obtained for propranolol. Addition of an off-line LC separation using a 1-mm LC column with fraction collection before spotting improved analytical sensitivity to 50 pg/mL.

The throughput of MALDI-QQQ clearly demonstrates the capability to acquire data representative of high throughput, even at the single analyte per spot rate; however, new bottlenecks such as spotting compound and matrix to MALDI plates would be added to the workflow, which require additional automation and degrade the overall process efficiency. Further, the original FlashQuant system lacked a plate-stacking capability, thus removing the capacity for sustained, unattended automated analysis.

Another laser-based methodology that has recently been introduced for high throughput quantitative MS is LDTD-APCI [94]. In this ionization source, 2–10 μ L of sample are spotted into a 96-well plate made of a polypropylene with stainless steel well walls. The plate sits on an x – y translatable stage, and the sample is moved to align with the source assembly. Once in position, a plunger from the source is placed into the well to seal off the sample well. An infrared (IR) laser thermally desorbs analyte into the vapor phase; vaporized sample is swept through a transfer tube by a carrier gas (air), to a corona discharge needle for ionization, before sampling by a mass spectrometer.

Wu *et al.* monitored competitive inhibition for the CYP isozymes 1A2, 2C9, 2D6, and 3A4 using human liver microsomes. For the metabolic probe molecules monitored in this study, acetaminophen, 4'-hydroxydiclofenac, dextrophan, and 6 β -hydroxytestosterone, the signal obtained for 5 μ M of each analyte in 0.25 mg/mL human liver microsome data were similar and, in some cases, better than data generated by flow-injection with APCI or ESI. When operated in fully automated mode, a 96-well plate was analyzed in 18 min for a sample throughput of 11.3 s per sample.

19.16 THE FUTURE PROMISE OF AMBIENT IONIZATION METHODS

During the past five years, many new ionization techniques have been introduced in the field of MS, which enable direct analysis of samples with minimal or no sample clean-up. These ionization techniques have been classified as ambient ionization techniques. The fundamental principles and applications for ambient ionization are described in more detail in this volume in the chapter titled *A Perspective on the Evolving Field of Ambient Ionization Mass Spectrometry*. An inherent advantage of these techniques is the generation of ions in an “open-source” before transmission into the mass spectrometer; thus, samples can be introduced from alternate technologies to the mass spectrometer (i.e., from glass slides or capillaries, thin-layer chromatography (TLC) plates, or paper). The major constraint for analyzing a batch of samples is physically introducing the samples (on a sampling device) to the mass spectrometer.

A second potential advantage these techniques offer is eliminating time spent developing a specific separation method along with concomitant reduction in SRM method development time.

DESI and DART have been utilized to provide quantitative information at increased throughputs from biological samples. Initial reports demonstrated many utilities of the DESI source for the detection of specific analytes from a variety of surfaces [95]. The high throughput capabilities were demonstrated by moving pharmaceutical tablets using a conveyor belt at a rate as fast as 0.33 s per sample [96]. For liquid samples, a DESI source with a 3D stage (automated in two dimensions) has been developed and interfaced to a linear ion trap mass spectrometer by Manicke *et al.* [97] (Fig. 19.6). They demonstrated the ability to analyze samples containing either propranolol (PRN) or carbamazepine (CBZ) at a sampling rate of 2.5 s per sample for analytes in 10% urine or porcine brain total lipid extract from a 96-sample array plate for with a total analysis time of ~ 3 min per plate. Moreover, good precision data were obtained for the chosen analytes: relative standard deviation (RSD), 10% from urine and $<5\%$ from brain lipid extract with deuterium-labeled internal standards. Full scan MS mode enabled a limit of detection of 10 fmol for PRN from a neat solution and increased to 400 and 200 fmol for 10% urine and brain lipid extract samples, respectively. As expected, the biological extracts increased the observed chemical noise. Notably, these detection limits could have been markedly improved with the use of MS/MS scan on the ion trap or a triple quadrupole operated in SRM mode.

One key attribute of DESI is the low protein ionization efficiency, compared to small molecules and peptides, resulting in the potential for very little sample preparation before analysis. Additional ionization modes may be explored, such as desorption atmospheric chemical ionization (DAPCI) [98]. An automated DESI source coupled to a tandem mass spectrometer would be highly applicable for a full suite of *in vitro* ADME techniques, once automated plate handling coupled to the source and automated spotting from 96- and 384-well plates were implemented. For example, for metabolic stability, samples from various time points could be analyzed quantitatively and qualitatively using the same sample spots if Q-TOF, linear ion orbitrap, or quadrupole ion trap mass spectrometers were utilized. Using many of the same principles discussed above (sample pooling and using multiple probe molecules), CYP inhibition assays could be performed at the fastest cycle times ever recorded.

The DART ionization source developed by Cody *et al.* [99,100] has also been shown to perform well in a variety of qualitative and semiquantitative analyses. Liquid

Figure 19.6 (a) A schematic diagram of the automated 2D stage DESI sampling system, as described by Manicke *et al.* [97]. The “96-well” layout is composed of a glass slide and raised printed hydrophobic ink containing polytetrafluoroethylene (PTFE) in the geometrical arrangement of a standard 96-well plate. The custom built X–Y moving table aligns the appropriate spot to the DESI sampling probe for analysis, following positional and incident angle alignment of the DESI tip. (b) The sampling rate of the system of 1.5 s per sample from neat solutions, composed of 0.5-s interwell movement and 1 s of spot analysis. Propranolol (PRN) (solid line) and propranolol-*d*7 (PRN-*d*7) internal standard (dashed) chromatograms are shown from an expanded region of the 96-well plate analysis. (c) The representative calibration curves (intensity ratio vs concentration for propranolol) generated from neat solutions of propranolol and stable labeled internal standard ($N = 5$ replicates per concentration level). Error bars indicate reproducibility (%RSD) of 5–10% for the lowest standard and $<5\%$ at other concentrations.

(b)

(c)

samples are introduced into the ionization source region using a glass TLC micro-capillary tube, solvent is evaporated, and ions are generated by chemical ionization processes. Cycle times in the <5 s per sample regime have been shown, from the time of sample introduction until complete evolution of the analyte from the tube. With these principles in mind, Yu *et al.* [101] developed a DART source interfaced with an automated sampling system to enable analysis of drugs from plasma samples using a triple quadrupole mass spectrometer. A critical modification to enhance the sensitivity of the DART source was an additional pumping interface between the exit of the DART source and the entrance of the ABI 4000 mass spectrometer. This reduced the gas load of He produced by the DART source to enable sufficient pumping by the mass spectrometer and contained analyte enriched carrier gas to the API interface. The second improvement involved automating the procedure for transferring sample from a plate to the ionization region using a HTC-PAL autosampler with a glass dip tube instead of a syringe for sampling.

Matrix effects varied for each analyte. For example, prapracaine gave a response of 5.4% of the neat solution response when sampled from plasma. Linearity was achievable for the compounds studied, and the sensitivity was within the range that was usable for bioanalytical studies, that is, verapamil was detectable at a level of 0.1 ng/mL. The overall sensitivity was 2–10 times lower than that achieved by electrospray for the compounds surveyed. The cycle time for each sample was at ~0.8 min per sample. The sampling rate was dictated by the speed of the HTC-PAL for fetching and placing samples into the source. This time could be further reduced using a multiplexed HTC-PAL system in which the next sample could be dipped while the current sample is analyzed.

The authors noted that DART ionization is unable to maintain intact glucuronide conjugates during the ionization process, thereby yielding higher apparent amounts of the parent molecule. Moreover, the system is limited to analyzing molecules with a molecular weight (MW) of <1000 Da.

Recently, IonSense has announced a 3D sampling stage for the DART source, the SVP 3+D scanner at the 2010 Pittcon Conference (Musselman 2010, Personal communication). It is likely that cycle times for this implementation of DART will compare favorably with DESI and FlashQuant.

The application of laser-based and ambient ionization techniques can truly increase the throughput achieved by quantitative MS. By eliminating the LC, the complexity of the analytical system is reduced. These techniques show great capability to reduce sample analysis times from minutes down to seconds. However, for these techniques to be successfully implemented, mechanisms to automatically handle plate loading and removal from the source region must be made available along with the ability to store and access a large number of plates. Moreover, new advancements in data handling and processing will also need to be developed.

19.17 SUMMARY

The realization of high throughput quantitative MS has required a significant internal investment of resources for the development of customized workflows and human interfaces. In many instances, the techniques being employed have achieved the 1–2 s per analyte goal of “high throughput,” most notably in minimizing the dead time associated

with each discreet event and removing manual processes. A number of inefficiencies still remain within the process, most notably the LC separation time domain and post-analytical data review. The nascent potential of ambient ionization methods may play a significant role in eliminating these steps to match the analytical throughput of the mass spectrometer. Recently developed instrument-independent quantitative peak processing tools may also further align these throughput efficiencies.

20.1 SUMMARY

The ultimate goal of drug discovery and development is to find the right drug and to administer it at the right dose with the right frequency to the right patient. Biomarkers can be an invaluable tool to meet this goal by confirming the efficacy and safety of drug candidates, enabling the understanding of their mechanism of action (MOA), and determining the efficacious dose and dosing regimen by establishing the correlation between the pharmacokinetics (PK) and pharmacodynamics (PD) of the drugs. They can also aid the selection of a patient population that will respond to treatment and benefit the most from their therapeutic effects, thus creating the path for personalized medicine. Biomarkers are objectively measured indicators of pathogenic processes of disease development or responses to therapeutic intervention. This chapter provides a brief description of the key concepts related to the use of biomarkers in pharmaceutical drug discovery and development. The role of target, mechanism, outcome,

and surrogate biomarkers in the early stages of drug discovery, starting with target identification, nonclinical model development, through clinical translation and proof of concept (POC) applications are described. A brief section on PK/PD-model-based drug development and translational research illustrates how technological advances enabling more accurate and robust assessment of drug concentrations in target tissues and systemic circulation together with PD response data lead to more accurate human dose projections and more optimal clinical trial designs. Considerations for the characteristics of optimal PK/PD enabling biomarkers are presented, including study design and sampling considerations and an overview of the most commonly used methodologies for the development of quantitative biomarker assays. Since assay development and validation for biomarkers can take significant time and is expensive, the importance of biomarker validation using fit-for-purpose assays is discussed. The challenges and solutions to various aspects of the fit-for-purpose validation are described in the context of the drug development stage requirements. Throughout the chapter, historical perspectives and representative examples for the challenges, solutions, and applications of biomarkers are provided.

20.2 INTRODUCTION

Biomarkers have been used for over 100 years in medical practice and have been playing a key role in drug discovery and development for over half a century. The National Institute of Health Biomarker Definitions Working Group defined biomarkers as various biochemical, physiological, imaging, and behavioral characteristics that are objectively measured as indicators of normal or pathologic processes or in response to therapeutic intervention [1]. Perhaps, the two most well-known examples of biomarkers are blood glucose for insulin-dependent diabetes and low density lipoprotein cholesterol (LDL-C) for hypercholesterolemia and cardiovascular disease. Their history illustrates that the discovery, validation, and application of biomarkers in medical therapy and drug discovery require interdisciplinary research between biology, medicine, and drug development and can take several years to decades. The earliest records of diabetes can be found in Egyptian papyrus records in 1552 BC, mentioning frequent urination as the symptom, and from the eleventh century, diabetes was diagnosed by tasting the urine of subjects as its sweet taste was connected to the disease. However, it was not until the nineteenth century that the first chemical tests to measure sugar in the urine were developed. Furthermore, it took over 100 years of medical and biology research to discover and link insulin with type 1 diabetes, with the first successful treatment of a depancreatized dog with insulin occurring in 1921. The first home tests for urinary glucose became available in the 1960s, and Clemens' patented blood glucose meter in 1971, enabled the easier monitoring and medication management of diabetics [2]. Closer monitoring of the glucose biomarker levels combined with adaptive therapy, applying more frequent doses and self-adjustments according to individual activity and eating patterns, have significantly delayed the onset and progression of long-term complications in diabetic patients, thus illustrating the importance and utility of the biomarker in managing clinical outcomes for diabetes [3]. As for the history of LDL-C, the concept of using biomarkers in the prevention and treatment of cardiovascular diseases can be traced back to the Framingham study [4]. The investigators initiated this study in 1949 to "seek a single essential cause to produce cardiovascular disease."

It was soon realized that complex and multifactorial interactions lead to the pathogenesis of atherosclerotic cardiovascular disease. However, it was through this study that the quantitatively measured clinical parameters of total cholesterol and LDL-C as traditional risk factors for coronary heart disease were identified. Subsequent pharmaceutical research to identify drugs that inhibited cholesterol synthesis led to the discovery of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors that we now know as “statins.” Statins were approved in 1987 to lower total cholesterol and LDL-C, and in 1994, statins were shown to reduce cardiovascular events [5].

As illustrated by the above examples, there are a number of important roles that biomarkers play in clinical applications including diagnosis, monitoring disease progression or reversal, and patient selection for clinical trial stratification. In recent years, modern drug discovery has recognized the importance of biomarkers in the earlier stages of drug discovery and development. Their utilization is often required in compound selection strategies for nonclinical development using the efficacy and/or safety biomarker profile of drug candidates, as well as for the proof of medical hypothesis by linking drug effect to the biological target using relevant and validated target and mechanism biomarkers [6].

20.3 DEFINITION OF BIOMARKERS AND THE ROLES THEY PLAY IN DRUG DISCOVERY AND DEVELOPMENT

20.3.1 Target, Mechanism, Outcome, and Surrogate Biomarkers for Drug Discovery and Development

The drug discovery and development process consists of several stages. It starts with the identification of viable targets and continues with the screening and selection of potent drug candidates against the target. This is followed by testing these potential candidates to confirm their nonclinical *in vivo* efficacy and safety prior to proving their safety and efficacy in humans and ultimate benefit to the patients. In the candidate screening and selection process, it is important to demonstrate if a drug candidate is truly interacting with the target by directly or indirectly preventing it from performing its biological function, and if this interaction will result in modifying the disease. *Target biomarkers* provide feedback on direct inhibition of the target enzyme. *Mechanism biomarkers* provide information on the target inhibition, downstream from the target, in the disease pathway. *Outcome biomarkers* are indicative of the clinical outcome of the disease and are sometimes referred to as *surrogate biomarkers* since they are indicative of how the patient feels and functions. These concepts and definitions are illustrated by the examination of the well-known cholesterol synthesis pathway shown in Fig. 20.1. The first step in this pathway is the conversion of acetyl-coenzyme A to mevalonic acid (MVA) by HMG-CoA reductase. The target enzyme is HMG-CoA with the hypothesis that its inhibition will result in reducing blood cholesterol. MVA is the product of the first step in the enzymatic synthesis and thus is the target biomarker for this pathway. The other intermediates in this pathway are potential mechanistic biomarkers, while LDL-C is the outcome biomarker. On the basis of the results of the Framingham study, LDL-C has been validated as an outcome biomarker for cardiovascular disease. Since the connection between coronary heart disease and LDL-C is scientifically and medically well established, it is also accepted as a validated surrogate biomarker for

Figure 20.1 Schematic of the cholesterol biosynthetic pathway. Mevalonic acid is the target biomarker for the conversion of HMG-CoA by HMG-CoA reductase [19].

this disease. Validated target, mechanism, and outcome biomarkers are invaluable in drug discovery and development as they can lead to earlier validation or disqualification of a new target, provide feedback on drug design and selection, and save significant time and cost. For instance, by demonstrating that a drug candidate “hits” the target via inhibiting the formation of the target biomarker, but results in no modulation of the outcome biomarker that has been linked to the disease state, a target can be proved nonviable. Similarly, if target modulation was not achieved *in vivo* then this information can be provided to the medicinal chemist to design and synthesize more potent candidates. Another benefit is time and cost savings. For instance, confirming modulation of cholesterol synthesis by measuring the steady state concentration of systemic LDL-C can take four to six weeks, while potent inhibitors of HMG-CoA show modulation of the target biomarker, MVA, less than 24 h post dose in the blood of patients, thus enabling the evaluation of potential novel compounds much faster and at lower cost. As illustrated in Fig. 20.2, acute changes in plasma mevalonate levels have been demonstrated to correspond to the potency of statins. In addition, since the target organ for statins is the liver, plasma drug concentrations can be difficult to measure, so the plasma biomarker modulation facilitates the assessment of target inhibition. Therefore, plasma mevalonate can be used in succinct nonclinical PK/PD modeling studies to select an efficacious dose and is translatable from nonclinical models to humans.

20.3.2 Disease Biomarkers and Diagnostic Markers

As described above, outcome or surrogate biomarkers that are well understood and validated for a given disease state can be utilized to diagnose or confirm a disease. It is

Figure 20.2 A relationship exists between the change in mevalonic acid (MVA) area under the curve (AUC) following a single dose of statins in healthy subjects and steady state changes in LDL-C in patients.

important to note that the normal range of some biomarkers can have significant inter-subject variability. Therefore, it is not the actual biomarker levels, but changes to these levels, that are diagnostic of a developing or advancing disease state. For instance, until recently, research on one of the most widely used tumor biomarkers, prostate-specific antigen (PSA) for prostate cancer, suggested that the rate of increase in PSA (the PSA velocity) was a more specific marker for prostate cancer than the absolute blood levels [7]. Thus, it was recommended that baseline levels were established for subjects in the higher risk populations and monitored for changes with a given frequency (i.e., approximately two years). The rate of PSA increase is also believed to have a value in prostate cancer prognosis. For instance, men with prostate cancer whose PSA level increased by more than 2 ng/mL in a year before the diagnosis have a higher risk of death from prostate cancer despite surgery [8]. Most recent PSA diagnostic tests approved by the Food and Drug Administration (FDA) between 2000 and 2010 are actually used to determine the ratio of free PSA to that of total PSA, including the fraction that is bound to serum proteins. In men with prostate cancer, the ratio of free to total PSA is decreased, and the risk of men acquiring cancer increases if the free to total PSA ratio is less than 0.19–0.25 [9].

20.3.3 Biomarkers for Patient Selection and Trial Stratification

A great promise of modern drug development is personalized medicine that enables the physician to select the treatment most beneficial to the patients to cure, or slow down the disease with the least amount of risks from unwanted side effects. Biomarkers, often codeveloped and validated as a diagnostic, with a given therapeutic can enable the selection of the patients who are most likely to respond to the treatment, thus obtaining

the most benefit. The development of companion diagnostics became possible because of the increased understanding of the role that particular genes play in the disease pathology.

Examples of this for cancer are Herceptin[®] that is approved for the treatment of human epidermal growth factor receptor 2 (HER2) overexpressing breast cancer tumors, as well as Vectibix[®] and Erbitux[®] that are approved for V-Ki-ras2 Kirsten Rat Sarcoma viral oncogene homolog (KRAS) expressing colorectal cancer. The cytochrome P450 genotyping test approved in 2003 by the FDA using gene chip arrays can be used to determine if a patient has mutations in their CYP4502D6 gene that can affect their ability to metabolize certain drugs, which can lead to harmful drug–drug interactions or inappropriate dosing and treatment. Human gene expression analysis already plays and will continue to play an increasing role in the identification and validation of new disease targets and the development of individualized medicine with more effective and safer treatment options [10–12].

20.3.4 Pharmacodynamic Biomarkers

Biomarkers are also a means to assess PD response. Their use in understanding effect and exposure relationships is essential for PK/PD-model-based drug development enabling better predictions of efficacious dose and regimen [13–16]. Target and mechanism biomarkers that are directly linked to a target's activity or its MOA through a given biochemical pathway or outcome can potentially be used as PD markers. Their full utilization requires translatability between nonclinical models and human, validation of the animal models for nonclinical *in vivo* efficacy screening, as well as confirming the MOA in POC clinical studies. Blood concentrations of drug as a result of therapeutic dosing have long been assessed to determine PK parameters; thus, they can be considered a biomarker of dose response. On the other hand, in some cases, the blood concentrations of drug cannot be measured because of exposure levels below the limits of detection of the technology used or rapid conversion of the parent drug to metabolites. In these instances, PD biomarkers are often recommended to help to establish tolerated doses and dosing regimen.

20.4 PHARMACOKINETIC/PHARMACODYNAMIC-MODEL-BASED DRUG DISCOVERY AND DEVELOPMENT

20.4.1 PK/PD-Model-Based Drug Discovery and Development

The goal of PK/PD modeling is to link the drug exposure to the pharmacologic response and thus determine the optimal dose and dosing regimen to attain and maintain an efficacious concentration for successful treatment. In recent years, significant advances have been made in this area due to the development of more robust bioanalytical methods to determine PK parameters by measuring circulating drug concentrations systemically and in target organ tissues, as well as measuring biochemical PD biomarkers. An example of this is the use of physiologically based pharmacokinetic (PBPK) models to characterize multivariate systems [13]. PBPK modeling is a mathematical modeling method that is used for predicting the absorption, distribution, metabolism, and excretion (ADME) of a compound *in vivo*. PBPK models are also usually multicompartiment models in which the compartments correspond to predefined organs

Figure 20.3 Translational research process illustrating the bidirectional and iterative integration of nonclinical basic research (learning) and its application after clinical translation (confirming).

or tissues in the body, and the interconnections correspond to blood or lymph flows. Measurement of drug concentrations systemically (in plasma or serum) and in the target organs, as well as biomarkers that correspond to the PD response in these same compartments, enables the development of more robust PBPK and PBPK/PD models resulting in better predictions of optimal dose.

20.4.2 Translational Research

Translational research is a recent interdisciplinary approach that focuses on successfully advancing fundamental discoveries from the discovery to clinical setting, and is often interpreted to include a bidirectional component where clinical findings are integrated back into the nonclinical space [17–19]. More broadly, this bidirectional component can be interpreted to include a ‘learning and confirming’ model of iteratively increasing and applying knowledge from nonclinical to clinical testing [20]. The basic components of this translational research process are illustrated in Fig. 20.3. Owing to the sequential process of drug discovery and development from *in vitro* and *in vivo* nonclinical models to human, it is paramount that the translatability of nonclinical knowledge to clinical relevance, and vice versa, is well understood and integrated in a successful and more efficient drug development process.

20.5 PK/PD ENABLING BIOMARKERS

As defined previously, PD is the science of drug action on an organism. It may be studied at many organizational levels (molecular, cellular, tissue/organ, and whole body) and at all stages of the drug development process. In addition, by enabling the quantitative integration of information across different species and throughout the clinical phases of development, PD measures can be represented by a number of

TABLE 20.1 Characteristics of Optimal PD Biomarkers

Biomarker Attribute	Desired Characteristic for PD Modeling
Mechanism of action	The biomarker's connection to the mechanism of action and disease state is well understood and correlated
Translatability	Biomarker is expressed in nonclinical models and clinical subjects and is correlated with the mechanism of action
Biological variability is well understood	Intra- and intersubject variability is well understood, the range of biological variability is low relative to modulation with disease state and drug effect
Accessibility in biological matrix	Sample collection is noninvasive, small sample size preferred
Measurability	Objective, quantitative techniques can be applied

different biomarker classes and utilize a wide range of laboratory and analytical techniques. Therefore, as an integral part of PK/PD modeling, the selection of effective PD biomarkers has become an essential strategy to optimize drug development resources.

20.5.1 Characteristics of Optimal PD Markers for PK/PD

When considering a PD biomarker for conducting modeling and simulation in pharmaceutical development, there are several attributes of the biomarker that would be regarded as ideal for this purpose (Table 20.1). Among these traits are its linkage to the drug/target MOA and linkage to the disease state, translatability between nonclinical models and the clinic, biological variability and modulation, and accessibility for sampling and measurement. For example, plasma and urine concentrations of MVA have been shown to correlate with the biosynthetic rate and long-term changes of cholesterol levels in nonclinical models and humans [21–24]. Therefore, determining the concentration of MVA in these accessible (peripheral) biological fluids can be used as a mechanistic biomarker of HMG-CoA reductase inhibition localized in a sequestered cellular target space (e.g., liver) and can thus provide a quantitative link between target and outcome (cholesterol level). In addition, information that has been collected on PD biomarkers that have been successfully translated to the clinic can be fed back to discovery efforts to further optimize drug candidates and nonclinical models [25]. The biomarker should also reflect the underlying biology by demonstrating a measurable impact on the biological mechanism or pathway that confirms a drug target has been hit and is having a correlating effect on the disease outcome [26]. In this regard, biomarkers that are more proximal to the drug target, rather than distal clinical end points further down the disease pathway, may be more desirable because they could minimize the influence of potential intervening variables between the target and outcome.

An ideal biomarker for effective PD modeling purposes should not be subject to a large amount of “noise.” Biological variability, such as marked circadian and diurnal rhythms, food effects, induced stress, or various disease states, may mask changes in biochemistry that are caused by a mechanistically based drug intervention [27]. The biomarker should also have an adequate modulation window between treated and non-treated subjects, dosed groups, or healthy versus diseased, so that a change can be

quantified relative to inherent accuracy and precision errors of the employed analytical methodology. It is also beneficial if the biomarker can be quantified with objective versus subjective techniques. For example, clinical trials for pigmentary disorders involve measurement of melanin. Melanin is a highly insoluble pigment of varying composition that is not particularly amenable to commonly used quantitative methods. Therefore, instruments that measure the ratio of reflected light to incidental light from skin, such as reflectance spectrometers and tristimulus colorimeters, are increasingly being used by dermatologists for the quantitative measurement of melanin [28]. While this approach can provide noninvasive information for the melanin content of skin *in vivo*, interobserver bias or characteristics of a particular instrument's aperture limit the accuracy and reproducibility of these measurements. Therefore, a biomarker that can be developed, which reflects the skin melanin content in absolute quantitative terms, such as pyrrole-2,3,5-tricarboxylic acid (PTCA), could be a more desirable methodology. Once melanin is oxidized to its unique monomers, such as PTCA (Fig. 20.4), melanin content can then be accurately determined by validated analytical technology such as liquid chromatography tandem mass spectrometry (LC-MS/MS). These more objective measurements of melanin concentration in skin are less susceptible to interobserver or instrumental bias and can provide more reliable PK/PD modeling. Another important consideration is to understand how the concentration of a particular biomarker can be influenced by the external influences (such as diet), endogenous biosynthesis rates, and interacting biochemical pathways. Static (as a single time point) and kinetic (as multiple time point or time course) measurements can provide more insight into the turnover and synthesis rates [29]. For instance, it is well known that carbohydrate and fat intake can affect the plasma lipid profiles. Measuring the lipid concentration at a single time point (static concentration) provides a snapshot in time, but it does not reveal the origin of the lipid (endogenous vs dietary). Stable isotope tracers combined with static and dynamic (metabolomic and fluxomic) measurements can provide a more complete assessment of the biomarker modulation [29,30].

There are also practical considerations when considering an optimal PD biomarker for PK/PD. A biomarker that can be obtained in a noninvasive manner from a matrix that is easily accessible and is relatively abundant has several advantages, such as being more cost effective because of ease of sampling, the use of fewer study subjects, and greater clinical study compliance [31]. Biomarkers requiring a small sample size for their quantification also facilitate the ability to collect more time points from the same subject. This advantage is compounded if several relevant biomarkers can be multiplexed into a single quantitative analytical method. Similar to xenobiotic analysis, it is also important to assess if the biomarker has issues that could complicate sample handling, such as stability or induced changes post collection, which may interfere with accurate endogenous measurements. Finally, in a resource-constrained environment, quantitative method development for the analysis of biomarkers tends to be tool driven. Therefore, when a biomarker must be available in time for the intended use in a program, some classes of biomarkers may be prohibitively difficult to quantify accurately because of their molecular composition and the available technology.

20.5.2 Fit-for-Purpose PK/PD Markers

Developing and applying PD biomarkers for mechanistic PK/PD modeling and simulation imparts value and a quantitative basis for translational research throughout the

Figure 20.4 (a) Melanin can be oxidatively degraded to its unique monomers which are more amenable to common quantitative analytical methodology such as LC-MS/MS. (b) Noninvasive chromametric measurement. Melanin can be measured noninvasively using light reflecting technology to provide subjective pigment measurements, with lighter skin color reflecting more light and thus giving a larger calculated *L* value (arbitrary value obtained from chromametric measurement). (c) Comparison of PTCA concentrations obtained from different skin types. However, more objective and quantitative levels of melanin can be determined using LC-MS/MS following its conversion to PTCA monomers in 2-mm skin punch biopsies. *Source:* Part (b) and (c) graphic courtesy of Kim Wade.

drug development pipeline. The intent of this approach is to provide informed decision making in early drug development that can be applied at later stages to reduce cost through smaller study sizes or duration. Therefore, it is important to develop biomarkers, as well as the analytical tools for measuring them, that are fit for the purpose of answering the PD question that is being posed.

The desired characteristics of fit-for-purpose biomarkers depend on their intended use and the stage of drug development. For example, biomarkers selected to validate a therapeutic target or mechanism may not be appropriate for accurately scaling dose predictions across species or to form the basis of clinical trial simulations. Once the degree of confidence in mechanism has been established for candidate drugs that have an effect on this target, then the utility of the biomarker at different stages in the drug development process can be considered. If monitoring the biomarker provides a high linkage between target/mechanism and predicting dose/outcome then this could potentially be used for later definitive nonclinical or clinical PK/PD study analyses using a validated assay. For example, androgen levels within prostate tumor cells may be used as target or mechanistic biomarkers for therapies, such as Abiraterone, developed to block intracellular CYP17 enzymes and thus combat castration-resistant prostate cancer [32]. These steroid determinations may be highly useful early on in drug development to demonstrate proof of mechanism and validate the target in xenograph or *in vitro* systems. However, because of the invasiveness of sample collection, analytical challenges in their measurement, and narrow modulation window, other biomarkers such as PSA may be needed for later stage PK/PD studies and patient treatment decision making.

20.5.3 Utility of Quantitative and Qualitative Biomarker Assays

At the cellular and whole animal level, drugs can act on many biochemical pathways and in many target tissues. These actions could lead to primary responses which, in turn, may induce secondary responses, that can either enhance or diminish the primary response. Systems biology is an emerging discipline that evaluates how individual components of a complex biological system dynamically interact within the system [33]. When given a pharmacological treatment that is aimed at single components of a pathophysiological process, systems biology can provide a collective understanding of how the whole system is affected. If effectively integrated in early drug discovery and hypothesis driven, systems biology could offer an understanding of the MOA of new molecular entities, allow the modeling of different pathways individually, and estimate their overall contribution to the net effect.

Therefore, when doing studies to understand systems biology and PD hypotheses related to early validation of a disease target, more multiplexed or qualitative assays could be more appropriate than a highly accurate and precise quantitative method developed for a single biomarker. The application of “polyomic” technology, such as genomics, proteomics, lipidomics, and metabolomics, offers the potential to generate more successful drug candidates because each technology offers more extensive and complementary approaches to the underlying biological and pathological processes being examined [34]. While producing large quantities of biological data, there is already evidence that these tools can be used to detect specific changes that predict disease and drug response [35–38]. Often without reference standards, or with the goal of doing a pattern comparison between a panel of biomarkers from diseased versus healthy or treated subjects, it may be adequate for scientists to use relative quantitative

or semiquantitative assays [27]. An understanding of the basic attributes of the individual technologies, for example, sensitivity and signal-to-noise, is required to determine their applicability. For example, microarray tools that provide a comprehensive survey of the cellular transcriptional landscape and identify gene expression patterns can predict or monitor drug responses. Advances in mass spectrometry (MS) have allowed scientists to monitor protein expression changes and correlate them to disease progression. Similarly, many imaging modalities, such as magnetic resonance imaging (MRI), have been successful for qualitative biomarker analysis.

20.5.4 Study Design Considerations for Biomarkers

The biomarker strategy should be integrated with the PK/PD strategy of a program to understand confidently the relationship between dose and the time course of biomarker response. Drug exposure and biomarker response relationships *in vitro* and in nonclinical species must be understood in order to enable PK/PD modelers to evaluate the effect of time on response (e.g., modulation window, delayed biomarker responses or responses lasting longer than exposure) and will have impact on the protocol design of the studies. Therefore, the utility of the results from a PD study can only be maximized when the study design considerations for biomarkers are adequately considered.

For an ideal PD biomarker, the signal should be quantitative and reflect activity of the compound in the tissue of interest, which is relevant to the indication. The biomarker response should also be evaluated over a wide range of doses and exposures in single and/or multiple dose studies and include sampling times that provide an understanding of the relationship between time of dosing (i.e., exposure) to biomarker response. Similarly, the relationship between biomarker response and efficacy must be understood to establish the degree of biomarker signal associated with the desired outcome. This will also establish the dynamic range, or modulation window, required for the biomarker assay. In addition, whether intermittent high levels of pharmacological activity or constant levels of pharmacological activity are preferred for efficacy must be correlated to the biomarker disposition. This may come from nonclinical models, or from studies that compare the biomarker signal in normal subjects with various levels of disease activity [25]. Some direct pharmacological effects may not be rapidly reversible or may have irreversible downstream effects on the disease. For example, repeated dosing can result in toleration, sensitization, or various reflexive feedback mechanisms. Therefore, doses selected should result in clearly separated levels of pharmacological activity based on biomarker data and exposure–response modeling [38].

There are a number of other factors, both intrinsic and extrinsic, that may affect biomarker calculations that should be considered when designing PK/PD studies [27,39,40]. For example, animal species and biological sample size (i.e., animal size) or availability may limit the amount of biological sample that may be collected from each subject and may increase the number of subjects needed for each study or necessitate the use of highly sensitive, low sample volume assays. The utilization of dried blood spot sampling for biomarkers can certainly facilitate the collection and storage of test samples [41]. Multiple mechanistic biomarkers of interest, or biomarker and drug measurements, may need to be multiplexed into a single assay method to adequately cover peak/trough analyte levels. In addition, in order to account for intra- and intersubject variability in drug effect at each time point, it is important to characterize the entire biomarker sampling interval with and without drug on board.

Variation in biomarker levels from time to time, be it from reproducible rhythms (circadian/diurnal), food effects, disease state, and so on, make it critical that the placebo biomarker response profile is understood so that changes in the biomarker during drug intervention are not attributed to drug activity when they are really just biological variability. It may be necessary to draw predose samples from each subject if significant intersubject biomarker variability exists at the beginning of a study. Finally, proper sample collection and handling strategies, beyond those assessed as part of an analytical method validation, must be evaluated to determine their effect on biomarker variability. Matrix (e.g., plasma or serum), type of blood anticoagulant, immediate sample freezing or processing, platelet inactivation, and tissue or cell lysis protocol are some of the types of variables that need to be considered for biomarkers and implemented in a PK/PD study design.

20.6 ASSAY AND DATA QUALITY CONSIDERATIONS FOR PK/PD BIOMARKERS

As previously described, a biomarker can be a biochemical, physiological, imaging, or behavioral characteristic that is objectively measured as an indicator of a normal or pathologic process or a response to therapeutic intervention. In the context of this chapter, the primary focus is on biochemical markers. Biochemical markers can be characterized by a known chemical formula and structure and can belong to various compound classes, such as steroids, lipids, phospholipids, carbohydrates, nucleotides, peptides, proteins, and so on. The two primary methodologies for the identification of biochemical biomarkers are metabolomics and proteomics. Each of these comprises a comprehensive set of study designs and analytical technologies often in comparative studies between normal versus diseased and treated versus untreated study groups to identify differentially expressed biomarkers. Metabolomics primarily focuses on nonprotein, nonpeptide biomarkers and utilizes various sample extraction protocols followed by liquid chromatography (LC) and/or gas chromatography (GC) separation technologies combined with MS and/or nuclear magnetic resonance (NMR) detection. Proteomics, on the other hand, focuses on the identification of peptide and protein biomarkers using separation methods amenable to resolving larger molecular entities, including 2D gel and capillary electrophoresis, reverse phase high performance liquid chromatography (RP-HPLC), most often followed by matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) or electrospray ionization (ESI) LC-MS/MS detection. Once the biochemical biomarkers are identified, assays can be developed for their quantification. The two most often used technology platforms for this in body fluids and tissue extracts are immunoanalytical, or ligand-binding, assays and more recently, LC-MS/MS with the combination of immunocapture sample enrichment, or IMM-LC-MS/MS. This section provides information on the factors that determine which platform to utilize for biomarker quantification and discusses the key challenges of biomarker assay validation using these technologies.

20.6.1 Technologies for Biomarker Measurements

A variety of factors influence which technology platform should be used to develop a biomarker assay. These factors include technical feasibility, fitness for

purpose/validatability, translatability between nonclinical and clinical settings, throughput, availability at contract research organizations (CROs) to support larger scale clinical studies, and time required versus time available for method development.

Technical feasibility considerations should assess the selectivity and sensitivity of the method to accurately and precisely quantify the biomarker in the biological matrix relative to the biological variability and expected modulation of the biomarker. Biomarker concentrations with a significant modulation window between normal and diseased states and low intra- and intersubject variability can be differentiated using a method with greater variability, while highly variable biomarkers with a narrow difference between normal versus disease states have limited chance to be differentiated unless the method variability is minimized. Figure 20.5 illustrates this point for results obtained from a nonclinical study where animals were administered a statin drug and plasma mevalonate levels were monitored by LC-MS/MS. The modulation window between the low and high dose groups is a combination of the difference between the individual subject variability and the established assay accuracy.

Enzyme-linked immunosorbent assay (ELISA) and LC-MS/MS assay have inherently different selectivity and specificity based on the analytical principles they employ. The selectivity of a method is the measure of its ability to determine a particular analyte in the presence of other interfering components in the matrix. A method that is perfectly selective for an analyte is specific [42,43]. The inherent selectivity of immunoanalytical or ligand-binding assays, such as ELISA, is based on the selectivity of the antibody–antigen interaction. Antibodies are heterogeneous in their antigen specificity, which is attributed to the polyclonal B cell response that leads to their formation. This known heterogeneity, combined with variable affinity to the antigens, can cause considerable variability in the specificity and sensitivity of immunoassays.

Figure 20.5 Rat plasma mevalonic acid concentrations measured by LC-MS/MS following oral administration of a statin (rats 1–3: 10 mg/kg; rats 4–6: 100 mg/kg). Variability in a biomarker measurement comes from both technical and biological sources. Assay variability must be minimized when developing a method in order to accurately determine the modulation window of a biomarker in different states (i.e., healthy vs disease, treated vs untreated). The established overall accuracy error of the assay was 15% (represented by the dotted lines).

The three main contributors to the selectivity of an LC-MS/MS method are (i) sample preparation, including directed extraction of the analyte from interfering components; (ii) LC separation; and (iii) selected reaction monitoring (SRM) detection based on the precursor and product ion mass-to-charge (m/z) values. Thus, LC-MS/MS assays tend to be more specific than immunoassays. On the other hand, LC-MS/MS assays are limited to analytes with molecular weights below ~ 10 kDa, the m/z range detected by contemporary instrumentation. Most commonly used platforms are triple quadrupole mass analyzers with m/z ranges < 4000 . Using an ESI source that is capable of producing multiply charged ions can potentially bring small proteins within the useful m/z range of a triple quadrupole mass spectrometer. Other mass analyzers, such as time-of-flight (TOF) instruments, have a higher m/z range. However, they are often combined with ion sources, such as matrix-assisted laser desorption/ionization (MALDI), that are not amenable for quantitative measurements. Gas chromatography-mass spectrometry (GC/MS) can also be used for quantification of low molecular weight, highly volatile compounds.

A fundamental challenge in developing and validating robust quantitative biomarker assays, in contrast with assays for drug measurements, is the lack of relevant biological matrix that is devoid of the analyte(s) of interest. This not only requires an assessment of assay selectivity but also necessitates a strategy for preparing assay calibrators. Often a substitute calibrator matrix cannot be identified because of interfering components or because of inadequate analyte recovery compared to the biological matrix of interest. An alternative approach to remedy this issue that has been successfully applied to MS-based methods is the use of a stable-isotope-labeled isoform of the biomarker compound as the calibrator [44]. The incorporation of C^{13} , N^{15} , $2H$, or other heavy elements into the synthetic biomarker allows it to maintain similar recovery, chromatographic, and ionization properties as the endogenous form but provides the shift in mass to be resolved on the mass spectrometer.

In terms of sensitivity, ligand-binding ELISAs routinely reach 1–0 pg/mL sensitivity, especially using electrochemiluminescence (ECL) or fluorometric detection. LC-MS/MS assays have similar sensitivity in the 1–10 pg/mL and low nanogram per milliliter range depending on analyte responses and matrix effects. More recently, immunoaffinity enrichment using analyte-specific antibodies has been coupled with LC-MS/MS analysis to increase the sensitivity [45]. There are also significant differences in the precision and accuracy of the various platforms. Immunoassays usually have greater variability because of their simple sample preparation procedures that often use straight, or minimally, diluted plasma or serum, and have inherent specificity and potential cross-reactivity issues. Commonly, for validated ELISA assays, $\pm 20\%$ accuracy and precision with $< 30\%$ total error is acceptable. LC-MS/MS assays, on the other hand, use more elaborate sample preparation procedures and utilize an internal standard to correct for process and analysis variability and, therefore, are usually validated within $\pm 15\%$ accuracy and precision criteria. The main characteristics of various assay technologies that can be used for biomarker quantification are shown in Table 20.2. Besides the technical considerations listed above, some logistical consideration such as typical development time lines are also included.

20.6.2 Fit-for-Purpose Assay Validation Considerations for PK/PD Studies

While biomarkers are increasingly used in internal decision making within pharmaceutical companies, there is a focused interest in their utilization for regulatory evaluation

TABLE 20.2 Comparison of Assay Characteristics for Commonly Used Quantitative Biomarker Assay Technologies

Assay Characteristic	Ligand binding/Immunoassay	LC-MS/MS
Selectivity	Wide range of analytes Favored method for large MW proteins On the basis of antibody–antigen interaction Can measure multiple analytes nonselectively that cross-react with capture/detection antibody Can be multiplexed	Applied for <10 kDa MW polar/ionizable analytes On the basis of HPLC separation, molecular weight and fragment ion m/z values in selected reaction monitoring (SRM) detection Typically measures one specific analyte/SRM channel at a given retention time, can be multiplexed
Sensitivity	in picogram per milliliter	in picogram per milliliter to nanogram per milliliter
Precision (%CV)	<20	<15
Accuracy (%RE)	<20	<15
Throughput	Sample preparation in automated parallel processing, incubations: few hours to overnight/96-well plate Reading time: <5 min/plate	Sample preparation in automated parallel processing in <30–120 min/96-well plate LC-MS/MS analysis time: 2–15 min/sample
Sample preparation	Usually none, direct analysis of serum and plasma	Extraction, addition of stable-isotope-labeled internal standard
Reagent needs	Antibody reagents are needed; Labeling of reagents are required (source of variability)	Usually no specific reagents are needed; Stable-isotope-labeled internal standards may need to be synthesized
Equipment and sample analysis cost	Equipment cost is <\$100, 000 (~\$60/sample)	Equipment cost is <\$500, 000 (~\$100/sample)

Abbreviations: MW, molecular weight; CV, Coefficient of Variation; RE, Relative Error.

of new drug candidates. The FDA Critical Path Initiative outlines the framework and evidence needed to qualify biomarkers for regulatory drug evaluation purposes and defines some of the critical biomarker needs in various disease areas [19]. This need for high confidence in biomarker data used in scientific or regulatory decision making emphasizes the need for high quality, reproducible, and reliable assay measurements that are translatable between nonclinical and clinical applications and validated for their intended purpose. In a recent conference, the American Association of Pharmaceutical Sciences (AAPS) Clinical Ligand Assay Society Biomarkers Workshop addressed the key challenges in biomarker research and summarized validation recommendations for immunoanalytical ligand-binding biomarker assays in a summary report [46]. Follow-up publications continued to discuss the need for iterative, fit-for-purpose approaches to biomarker method development and validation keeping in mind the intended use of the data, as well as the regulatory requirements associated with that use [43,47].

The fit-for-purpose concept advocates the progressive rigor employed for biomarker assays from initial characterization and qualification of assays to fully validated methods. Some of the key concepts related to this are described in the sections below and summarized in Table 20.3.

20.6.3 Assay Validation Versus Biomarker Validation

Regardless of which purpose the biomarker is used for, its successful utilization in scientific decision making requires its validation for the intended purpose. This fit-for-purpose validation consists of two critical steps: (i) the technical validation of the analytical method used to quantitatively measure the biomarker and (ii) the biological validation of the biomarker, confirming its linkage to the relevant biological and pharmacological hypothesis that is being tested. These two validation steps often occur concurrently, since a reliable analytical assay needs to be developed first to be able to test the biomarker's linkage to pharmacology in an animal model or human. Once the biomarker linkage to biology is tested and modulation of the biomarker between normal versus disease state or response to a therapeutic intervention has been shown, the analytical method requirements can be finalized and the method validated. Depending on the drug discovery program, multiple potential biomarkers in multiple animal models and species may be under investigation until a decision-making biomarker is selected. The development of multiple biomarker assays in multiple species and matrices and their testing in relevant disease models and clinical populations is a resource-intensive process with respect to both cost and time. Therefore, carefully designed and robust strategies for the development and fit-for-purpose validation of translatable biomarkers between nonclinical and clinical applications need to be formulated in the form of a biomarker research and operating plan [17,18]. The existence of this research plan containing input from nonclinical and clinical biology, pharmacology, PK, analytical, and PK/PD scientists can assure timely availability of validated biomarkers and assays to support nonclinical and clinical decision making.

20.6.4 Technology/Methodology Translation Considerations for PD Markers

The translatability of methods from the nonclinical to clinical application, including sample collection and preparation, is an important consideration for any biomarker—including PD markers. While it is not uncommon and often helpful to determine biomarker levels in the target tissues at the site of action in nonclinical models, the clinical applicability of these is limited because of the invasiveness of sample collection. In these cases, it is helpful to characterize the correlation between the tissue concentrations and circulating biomarker concentration in plasma, serum, or secreted concentrations in urine to determine if sampling from a less invasively obtained biological matrix can replace the tissue sample in the clinical setting. Other aspects for clinical translation are availability of the technology at CROs and throughput and validation requirements.

20.7 CONCLUSIONS/FUTURE CHALLENGES

The identification, analysis, and application of biomarkers in the development of therapeutics have come a long way over the past decades. The information provided by

TABLE 20.3 Characteristics of Fit-for-Purpose Ligand-Binding and LC-MS/MS Biomarker assays for Applications in Drug Development

	Drug Development Stage and Purpose of Biomarker Assay		
	Discovery	Nonclinical Development	Clinical Development
Assay Characteristic	• Identification of biomarker candidates • Use biomarkers for target validation • Evaluate biomarker response in animal model	• Validation of the biomarker's linkage to the disease state and/or mechanism of action • Characterization of the efficacy and safety in animal model • Drug candidate selection	Validation of the biomarker in human, for purposes of • Clinical trial go/no go decisions (mechanism, compound efficacy) • Clinical trial dose range determination (PK/PD) • Clinical trial design (length, size of population, powering of studies) • Compound differentiation • Disease diagnosis and prediction • Surrogate end points • Treatment decisions
Reference standard	Consistent—source determined	Stability as reference material and in biological matrix	Well-characterized (identity, purity) stability established, inventory/supply established
Assay dynamic range, LLOQ and ULOQ	Estimation based on endogenous levels and expected modulation	Verification based on incurred samples in animal studies, and in human, if feasible, if human assay is needed Establishment of LLOQ and ULOQ in multiple validation runs	Verification based on incurred samples Establishment of LLOQ and ULOQ in multiple validation runs
Selectivity and specificity	Determination based on reagent supplier or literature data, assess matrix effects, and potential interferences Determination of standard curve matrix (or surrogate matrix)	Verification of selectivity, specificity, and matrix effect in method validation runs	Verification of selectivity, specificity, and matrix effect in method validation runs

Precision and accuracy	Establishment of expectations for required accuracy and precision based on biomarker variability and expected modulation window	Determination of accuracy and precision in method validation runs (multiple runs for interassay values)	Determination of accuracy and precision in method validation runs (multiple runs for interassay values)
Recovery	Determination of recovery from biological matrix, establishment of expectations for desired sensitivity and robustness	Validation of recovery in spiked quality control samples and incurred samples	Validation of recovery in spiked quality control samples and incurred samples
Dilution linearity/parallelism	Verification if exist in incurred and spiked samples	Validation in spiked and incurred samples	Validation in spiked and incurred samples
Sample collection, processing, and storage stability	Establishment of feasibility, evaluation of stability at bench-top and in process	Establishment of bench-top and short-term stability, freeze/thaw, if used	Establishment of freeze–thaw and long-term stability

biomarkers to elucidate the drug target, biochemical mechanism, or disease outcome can be used nonclinically to predict efficacy and safety in humans. Therefore, biomarkers provide the cornerstone for PK/PD modeling and translational research. For proper design of PK/PD studies, biomarkers and the analytical methods used to measure them, require the degree of validation necessary to confidently answer the question the experiment was designed for. Technology also is advancing to the point where not only robust analytical methods for a PD biomarker can be established but mutianalyte and multiparameter assays (“-omics,” arrays, etc.) can also be developed to understand the PD system as a whole. Similarly, while some pharmaceuticals modulate well-established pathways and biomarkers, and can be applied to a population generally, such as statins, others require biomarkers to enable the selection, or stratification, of certain patient populations to demonstrate efficacy. While this systems pharmacology approach promises to lead to the design of better drugs with the right dose in the right patient, the amount of data generated and the associations that can be revealed are daunting. Therefore, bioinformatics will be an essential and integral part of future drug development to process and interpret large amounts of data. As biomarkers at the metabolome, genome, and proteome levels continue to be discovered, validated, and employed both for new drug development and in improving the utility of existing therapeutics, the next decades will no doubt bring more effective and safer therapies to patients.

21.1 SUMMARY

Phase 0 human microdosing trials are an approach that can obtain early human data in the drug development process and improve overall efficiency. A microdose of a small molecule is defined to be one-hundredth of the anticipated pharmacological dose or 100 μg , whichever is lower, or <30 nmol of a protein product. The microdose is designed to have cellular effects but not systemic or therapeutic effects and is intended to get basic pharmacokinetic (PK) data in a limited number of volunteers. Early human data can eliminate compounds with poor PK parameters early in the development process before major investments are made in later clinical trials. Better early information in phase 0 improves the planning process and pipeline efficiency, reducing the likelihood of needing to extend or repeat later clinical trials. The European Agency for the Evaluation of Medical Products (EMA) and the US Food and Drug Administration (FDA) support streamlining the drug approval process as long as

safety is not compromised and have issued guidelines on how phase 0 trials are to be conducted.

The low doses used in phase 0 trials present detection and quantitation challenges to conventional analytical instruments, especially when test compounds possess low bioavailability, low systemic distribution, or high potency. Accelerator mass spectrometry (AMS), liquid chromatography-mass spectrometry/mass spectrometry (LC-MS/MS), and positron emission tomography (PET) are bioanalytical techniques used for analysis in phase 0 studies. Each technique possesses strengths and weaknesses. LC-MS/MS is most common and least expensive. It is the easiest to use and can provide structural information on metabolites. It has limited sensitivity, however, and requires analytical standards for all metabolites. AMS has the best sensitivity and quantitative precision of the techniques. AMS quantitates a carbon-14 label but provides no chemical information, enabling detection of unknown or unexpected metabolites that must be identified with other techniques. AMS systems are rare and expensive, but off-site analysis is possible. PET provides unparalleled distribution information and real-time images of whether test compounds accumulate at targets. The positron emitters (carbon-11 or fluorine-18) used in PET have short radioactive half-lives and require an on-site cyclotron for production in addition to a PET scanner. PET is limited to short-term PK measurements and cannot distinguish metabolites from parent compound. Selection of a technique depends on the aims of the study and properties of the test compound. In many cases, combining the distribution information from PET with more quantitative measurements of AMS and LC-MS/MS provides the best picture of the behavior of a candidate compound.

21.2 INTRODUCTION

The current operational paradigm of drug development is time consuming and inefficient. Despite the great advances in biotechnology, computational power and models, analytical techniques, and genomics over the past 20 years, the rate of new compounds reaching the market has not increased. Furthermore, the pipeline lasts 10–20 years and costs of development are estimated at \$800 million to \$1800 million per registered drug [1–3]. As much as 40% of this cost is incurred in phase I trials that fail [4]. Up to 75% of this cost flows into compounds that never reach the market [5]. New approaches to drug development are needed to improve the efficiency of the development pipeline. Getting new compounds into humans earlier should reduce costs by identifying drugs destined to fail because of poor PK profiles before larger investments are made and by improving the planning of trials of those compounds moving ahead. Better informed planning should reduce the frequency of repeated or extended trials and potentially get new drugs to market more quickly. Phase 0 human microdosing trials are an approach that can obtain early human data [5].

A microdose is defined to be one-hundredth of the anticipated pharmacological dose or 100 µg, whichever is lower [6–8]. In the case of protein products, a microdose is limited to 30 nmol [7]. The microdose is designed to have cellular effects but not systemic effects and is intended to get basic PK data in a limited number of healthy volunteers. Phase 0 cancer clinical trials include patients with cancer, but doses of test compounds have no therapeutic effect [9–12]. Patients receive standard of care therapies during the studies.

Regulatory agencies in Europe and the United States support streamlining the drug approval process if safety is not compromised. The EMEA issued its Guideline on Microdosing in 2003 followed by a position paper on supporting nonclinical safety studies needed for microdosing [6]. The FDA followed with its Exploratory and Investigational New Drug Guideline in 2006 [7]. The guideline developed by the FDA Center for Drug Evaluation and Research (CDER) (2006) aimed to clarify the approaches, chemistry, manufacturing, and controls to be considered when planning exploratory studies in humans (also called *phase 0* or *preclinical trials*) [7]. It did not issue new regulations but rather interpreted existing recommendations on drug development. The FDA document describes three types of phase 0 studies: (i) microdose studies evaluating PK or imaging, (ii) studies evaluating pharmacologically relevant doses, and (iii) studies evaluating mechanism of action related to efficacy [7,13]. Multiple compounds can be administered in phase 0 trials allowing evaluation of several related compounds [13–15].

The aim of microdosing studies is to get drugs into humans earlier in the development process so that compounds destined to fail due to poor PK will be dropped before further investment is made [9–17]. The guideline delays full-scale good manufacturing practice (GMP) and some preclinical toxicity studies since microdosing uses very small amounts of material. There is no relaxation of good clinical laboratory practice (GCLP) when conducting phase 0 studies and full phase I studies must still be completed for compounds continuing in development [9,18]. Because very small amounts of test compound are used, quantitation challenges exist for measuring samples provided. In many cases, conventional LC-MS/MS cannot achieve the required sensitivity and either AMS or PET must be used to analyze the samples [14,18–23].

Beyond determining whether to continue development of a compound, early human PK and absorption, distribution, metabolism, and excretion (ADME) data provide insight for later human trials. By conducting phase 0 studies with intravenous (IV) and oral dosing, researchers can quickly assess bioavailability and address formulation before embarking on extensive trials [24]. The starting point and dose range for phase I can be selected with more confidence with early human data. Better early information in phase 0 improves the planning process and pipeline efficiency, reducing the likelihood of needing to extend or repeat later trials. In this case, an individual compound can get to market more quickly by minimizing delays, as it moves through the pipeline. Metabolite safety can also be addressed earlier with smaller doses of labeled drug [25].

Microdosing establishes PK of the subpharmacological dose. Lappin *et al.* [14,26] suggest that microdosing can predict pharmacological PK behavior. Although microdosing is not a perfect predictor of pharmacological PK, performing studies in the target species is often superior to allometry [17,27]. The collective experience of phase 0 trials is not yet sufficiently mature to predict when response will be linear across the entire dose range. It depends on whether receptors become saturated, reversible binding occurs, or first-pass metabolism produces an active metabolite [28]. A microdose is sufficiently small so that threshold, linear, or superlinear behavior cannot be distinguished.

Microdose levels of compounds labeled with short-lived radioisotopes appropriate for PET have been utilized for decades to determine tissue distribution. Isotopes appropriate for PET are produced with cyclotrons and then incorporated into tracer compounds. The chemistry must be done quickly because the isotopes decay quickly

and are very radioactive. The rapid decay of these compounds designed for PET works well for imaging of tissue distribution studies but is often unsuitable for PK studies.

The best way to measure the PK of these small doses is with an unambiguous tracer that can clearly be seen in small biological samples without knowledge of its metabolites. An atomic label that can be detected regardless of its chemical form is ideal. The radioisotope carbon-14 (^{14}C) with its low natural abundance ($^{14}\text{C}/\text{C} \sim 1$ part per trillion) is a fine candidate if the radiological hazards can be minimized. AMS is a rare isotope ratio mass spectrometry technique in which the rare isotope is a long-lived radioisotope such as ^{14}C . The technique is five to six orders of magnitude more sensitive than decay counting because it counts individual ^{14}C atoms in milligram-sized samples rather than waiting for their decay. The typical quantity of ^{14}C used in human metabolism studies is 200–40,000 Bq [29–32], comparable to the amount of ^{14}C in standard man (3700 Bq in 70-kg human) [33]. The small amount of isotope delivers lifetime radiation doses in the order of a couple microsievert, comparable to that received in a commercial airline flight across the United States. The level of radioactivity is so low that generally all samples (blood, urine, feces, and saliva) are nonradioactive, greatly simplifying waste disposal issues.

The strength of AMS is quantitative tracing of specifically labeled compounds. Metabolism studies are also attractive because the elevated ^{14}C provides an unambiguous signal that is clearly quantified. AMS does not provide chemical identification. That must be done by chromatography or other techniques before the tracer molecules are converted to a chemical form suitable for atom counting (either CO_2 or graphite).

Phase 0 trials require the high sensitivity to trace the small amounts of target compounds. Bioanalytical techniques suited for measuring experimental compounds are described below. All three techniques, AMS, LC/MS, and PET, have strengths and weaknesses. Selection of a technique depends on the aims of the study and properties of the test compound. In many cases, combining the distribution information from PET with more quantitative measurements of AMS and LC/MS provides the best picture of the behavior of a candidate.

21.3 BIOLOGICAL ACCELERATOR MASS SPECTROMETRY IN MICRODOSING

21.3.1 Overview of Accelerator Mass Spectrometry

AMS is an extremely sensitive analytical method used for the measurement of rare, long-lived isotopes. This technique was initially applied in isotope dating in the fields of archeology and earth science. More recently, AMS has been applied to the realm of experimental biology, including the areas of pharmacology and toxicology [34]. ^{14}C is the most common radioisotope used with AMS in biological studies, but ^3H [35], ^{41}Ca [36], and ^{10}Be [37] have also been used in biological AMS studies. The traditional analytical method of liquid scintillation counting (LSC) used in biological studies relies on nuclear decay events to quantify radioactive material. In contrast, AMS counts atoms of a rare isotope independent of decay by measuring the mass ratio of the radioisotope of interest relative to a stable isotope of the element. AMS is the most sensitive technique available for measuring ^{14}C , with the ability to quantify labeled material over six orders of magnitude down to the attomole (10^{-18}) level [34,38–40]. Owing to this

exquisite sensitivity, biological experiments using AMS produce negligible radiological exposure to the experimental subjects and do not perturb the normal biology of the system under consideration. The low level of radioactivity used in AMS experiments has enabled the use of human subjects in a number of biomedical tracer studies that would not be possible using other methodologies [34,39].

Studies in the biological sciences utilizing AMS include investigation of tissue turnover rates [41–43]; determination of PK parameters, including ADME, of drugs [14,21,26,44–46], toxicants [29,31], and nutrients [30,32]; measurement of the binding of drugs and reactive metabolites to proteins and DNA [46–48]; as well as risk assessment [49,50]. AMS is especially useful in microdosing studies because of its sensitivity that allows for the accurate measurement of extremely low levels of compound of interest. Measuring disposition and metabolism along with the molecular targets of investigational compounds in phase 0 studies can be done with AMS. Obtaining these data earlier in the drug development pipeline will help determine what compounds warrant further development. Those with unfavorable properties could be eliminated at an earlier stage before more is invested in a drug that has no chance of success. Microdosing experiments have made increasing use of AMS in recent years, introducing investigational compounds into humans earlier than is possible with more traditional techniques [14,26,51]. AMS is also being investigated for microdosing experiments with a growing area in pharmaceutical agents and biopharmaceuticals, which include large molecules such as polypeptides and proteins or macromolecules such as DNA segments [52,53].

21.3.2 Capabilities and Limitations of Accelerator Mass Spectrometry

Long-lived radioisotopes with low natural abundance are best suited for AMS measurement. Low natural abundance is important because the compound containing the radiolabel must be distinguishable from background levels, yet still be a low dose. The stable isotope ^{13}C does not fit in this category because it is naturally present in relatively high abundance, comprising approximately 1% of naturally occurring carbon.

AMS is unlike other forms of mass spectrometry in that it does not provide any structural information because the spectrometer is designed specifically for quantitation of the isotopes of a single element. Therefore, samples for AMS must be properly and adequately defined before analysis in order to ensure that meaningful results are obtained. The actual AMS measurement of a sample can be obtained in a few minutes; however, the sample preparation is a lengthier process and limits the throughput of AMS for ^{14}C analysis on most AMS instruments. AMS samples must be converted to a form that is easily conductive in the ion source and which does not allow for isotopic fractionation. Solid graphite is currently used on a conductive core such as cobalt or iron powder for ^{14}C analysis in most AMS instruments [54,55]. This proper sample definition presents a limitation of the technique, where a single HPLC trace may contain up to one hundred samples for AMS by graphitization [56]. The length of sample preparation and graphitization means several days pass between the time the samples are collected and the time that they are measured by AMS.

When sample material is plentiful and radiological dose is not an important consideration, other techniques such as LSC, isotope ratio mass spectrometry using ^{13}C , ^{13}C -NMR, or in some cases, fluorescent or chemical tagging of the compound or

molecule of interest may be more suitable than AMS. The level of sensitivity, importance of maintaining a low radiological dose, number and complexity of samples to be measured, and the cost of analysis are factors that should be considered in determining the appropriateness of using AMS for a biological study. The sensitive, quantitative, and precise nature of AMS makes it the most appropriate measurement technique for compounds with low bioavailability, low systemic distribution, or high potency. Experiments that require a compound in which only limited amounts can be produced or the tracer must be measured for extended periods of time are also well suited for AMS.

21.3.3 ^{14}C Measurement by Accelerator Mass Spectrometry

The majority of biological AMS experiments use ^{14}C because carbon is the basis of most biological materials and pharmaceutical agents. Recent developments have allowed for sample measurement in the gas phase; however, most AMS instruments measure samples in the solid state, which minimizes experiment-to-experiment carryover of signal in the instrument [57–59]. The solid form for measuring biological containing carbon by AMS is graphite. Samples containing 0.5–1 mg of carbon are optimal for graphitization and AMS, although samples containing 0.3–5 mg of carbon may be successfully measured [54]. In microdose applications, samples containing smaller quantities of carbon can be measured by the addition of a known quantity of carrier carbon that is ^{14}C deficient. The graphitization process consists of combustion of the biological sample to CO_2 , cryogenic isolation of CO_2 , and reduction to graphite in the presence of a cobalt or iron catalyst. The graphitization procedure has been described in greater detail elsewhere [54,55,60].

A schematic of a typical AMS instrument can be seen in Fig. 21.1. A cesium sputter ion source is used to generate negative carbon ions from the graphite sample. The ion beam containing those negative carbon atoms and other molecular isobars is mass selected following passage through a magnet and then introduced to the entrance of a tandem electrostatic accelerator. The ion beam accelerates toward and then collides with either a diffuse argon gas or a thin carbon foil that destroys interfering molecular isobars in velocity-dependent collisions and also removes one or more electrons from the atoms. The resultant positive ion beam is then further accelerated, followed by momentum and energy analysis. The rare ion (^{14}C) is counted using standard particle detection instrumentation. A change to the ion beam energy just after the ion source allows for the transmission of mass-13 ions through the first magnet and tandem accelerator with quantification of the $^{13}\text{C}^+$ ion current using an off-axis Faraday cup. This “bouncing” of the energy of the ion beam occurs several times a second allowing for the near simultaneous measurement of the $^{14}\text{C}/^{13}\text{C}$ isotope ratio of a sample. Absolute quantification of the $^{14}\text{C}/\text{C}$ isotope ratio in a sample comes from comparing the measured ratio of the sample to the measured ratio of similarly prepared standards.

Using the methodologies described, in a typical biological AMS study, a ^{14}C -labeled compound of interest can be routinely detected and quantified with 1–3% precision at levels ranging from ~ 10 pmol ^{14}C to 1 attomol (1×10^{-18} mol) of ^{14}C in samples containing 1 mg of total carbon in 5–10 min [38,54]. This measurement of ^{14}C by AMS can be compared to LSC that requires a gram-sized sample and a measurement time >48 h to obtain a precision of $\leq 1\%$. AMS is 1000 times more sensitive than LSC [61–63]. AMS experiments in humans have used ^{14}C label ranges from 185 Bq/person to 1.85 MBq/person, depending on the duration and type of study being performed

Figure 21.1 Schematic representation of the components of an accelerator mass spectrometer used to measure ^{14}C .

TABLE 21.1 Basic Performance Characteristics for the Biological AMS Instrument at Lawrence Livermore National Laboratory

Instrumental Performance	Approximate Value
Specificity (background signal with no ^{14}C)	Two parts per 10^{15}
Stability (loss of ^{14}C during sample preparation)	CV < 3%
Linear range of measurement	10^{-2} to 10^3 Modern
Instrument carryover between samples	None
Reproducibility	<5% error
Precision	2.5% (varies based on counting)
Lower limit of quantitation	5 amol ^{14}C
Upper limit of quantitation	100 fmol ^{14}C
Signal recovery	98%

[31,38]. The biological AMS instrument at Lawrence Livermore National Laboratory has measured over 70,000 samples during its operation over a period of nearly 10 years [64]. Important performance characteristics of this instrument are listed in Table 21.1.

21.3.4 Applications of Accelerator Mass Spectrometry in Drug Development

21.3.4.1 Basic Principles. Several basic principles can be applied to the unique experiments conducted with biological AMS to ensure that results are valid and informative. The investigator must understand what they are measuring by AMS. This understanding can be achieved by considering these three fundamental requirements for a successful AMS study:

1. absence of contamination in the sample,
2. appropriate amount of labeled compound, and
3. adequate sample definition.

Failure to satisfy one or more of these requirements of the sample can be very costly in time and resources and may entirely negate the value of the AMS experiment.

The absence of contaminating sources of ^{14}C is necessary to ensure that the measured ^{14}C is entirely due to the presence of the labeled compound being examined. Contamination can result in laboratory background levels as low as 5–10 μBq . The amount of labeled compound used in an experiment must result in a sample for AMS that falls within the range of 5 amol to 100 fmol ^{14}C in a milligram-sized sample. Samples with more than 100 fmol ^{14}C may generate a signal that exceeds the linear range of the counting electronics of the detector. Conversely, a sample that contains <5 amol ^{14}C will not produce adequate signal above background to be measured. Finally, the sample must be appropriately characterized by other methods such as HPLC before AMS in order to ensure that the correct and specific material of interest is measured because an AMS measurement provides no structural information. Chemical purity and radiopurity of the starting material should also be well characterized, typically using HPLC/MS and decay counting.

21.3.4.2 Work Area and Chemistry Requirements. The work area for conducting biological AMS experiments and performing sample preparation procedures must be clean and free of sources of ^{14}C -radiolabeled material as well as sources of extraneous

carbon. For AMS sample preparation, a laboratory that has no history of ^{14}C material use should be selected, as even microbecquerel quantities of ^{14}C can contaminate experimental samples [65,66]. The area for preparation of the radiolabeled compound must be separate from the dosing and sample collection areas. Samples to be sent for AMS measurement must also be stored separate from labeled material to prevent the possibility of contamination. The areas should be checked for ^{14}C background before beginning AMS experiments and must be monitored regularly for contamination. LSC is not sufficiently sensitive to detect contamination at low levels that can interfere with correct AMS measurement. Surveys for radioactive contamination should be taken and sent for AMS analysis in any laboratory in which samples are routinely prepared for AMS. The surveying procedure is described in greater detail elsewhere [65].

Chemicals to be used in experiments leading to the biological sample for AMS and the actual AMS sample preparation must be free of interfering radioisotope and should be sampled to determine the background ^{14}C levels by LSC and by AMS. Sodium-containing reagents should be avoided, as sodium can cause the quartz tubes used for graphitization to fail during the sample combustion step, resulting in loss of the sample. In many cases, it is possible to substitute potassium for sodium in reagents.

The major sources of potential errors encountered in AMS are the addition of carbon or ^{14}C from sources that remain unaccounted. This can be a result of contaminated solvents, glassware, laboratory equipment, airborne contamination, or even other researchers. The use of carbon-containing solvents for extractions or separations should be carefully considered in the determination of the total carbon present in the sample. Miscalculations in dosing or dosing of material that has an activity higher or lower than expected can result in excessive or inadequate signal intensity from the AMS sample.

21.3.4.3 Dosing and Collection of Labeled Material. The amount of ^{14}C -labeled compound necessary for adequate recovery and detection of signal by AMS can be approximated using several calculations. It is always advisable to perform initial experiments to optimize dosing, recovery, and detection parameters before beginning the full-scale AMS study. Performing these calculations and initial experiments will greatly increase the probability of obtaining meaningful results in the AMS study.

In estimating the doses of labeled compound that should be administered to achieve a desired degree of labeling in the collected sample, it is helpful to know the approximate bioavailability and volume of distribution of the compound under consideration. Although these parameters are unknown at the start of a phase 0 study, they can be estimated within one to two orders of magnitude for AMS signal-to-noise estimation. The type and quantity of tissue or other material (e.g., urine and feces) to be sampled should also be considered in the dosing calculation. For an experiment with an injected or highly bioavailable compound in which plasma is collected and the labeled compound is measured, the predicted optimal dosing level can be calculated as follows:

$$\text{Dose (in Bq)} = M_{\text{Target}} \times 226 \mu\text{Bq/mg C} \times V_{\text{Distribution}} \times C_{\text{plasma}}$$

where

M_{Target} = target fraction Modern in the collected sample, where
 $1 < M_{\text{Target}} < 100$

$V_{\text{Distribution}}$ = apparent volume of distribution for the compound (L)

C_{plasma} = carbon content of plasma (mg C/ μL).

The dose typically ranges from 300 Bq to 1.8 MBq. In the case of a compound with low bioavailability, the dose must increase according to the following equation:

$$\text{Dose (in Bq)} = M_{\text{Target}} \times 226 \mu\text{Bq/mg C} \times V_{\text{Distribution}} \times C_{\text{plasma}} \times (1/F)$$

where

F = bioavailability of the compound.

Predicted optimal doses can also be calculated for time points after administration of the labeled compound. In this case, the calculation is made based on the target fraction Modern for the final collection time point:

$$\text{Dose (in Bq)} = M_{\text{Final}} \times 226 \mu\text{Bq/mg C} \times V_{\text{Distribution}} \times C_{\text{plasma}} \times (1/F) \times e^N$$

where

N = number of elimination half-lives at the time of final sample collection.

These equations can be used for other materials (e.g., urine) by substituting the carbon content and tissue or fluid volume, as appropriate. When the target dose has been calculated in becquerel, the quantity of labeled compound (e.g., nmol) can be calculated based on the specific activity of the compound (nCi/nmol):

$$\text{Quantity(nmol)} = \text{dose} \times \text{specific activity}$$

The quantity of compound administered is typically in the range of 10–100 nmol.

For novel compounds, where little is known about bioavailability, volume of distribution, and elimination half-life, it may be necessary to perform initial range-finding experiments starting with low doses and working upward before conducting full-scale experiments. All samples with unknown levels of radioactivity should be quantified by LSC before graphitization and AMS analysis. Any sample that can be measured by LSC contains too much label to be measured by AMS.

Sample collection should be carried out using disposable materials, and care should be taken to avoid contamination or mixing of samples during collection, handling, and storage. Owing to the possibility of introducing contamination, separate sets of pipettes should be used for dosing experiments and for preparing samples for AMS analysis. If pipettes are used for dosing, they should not be used for general laboratory work or for preparing samples for AMS submission. Positive displacement pipettes and filter tips should be used at all times in all stages of experimental work and sample preparation to avoid the possibility of label carryover from one sample to the next. It is wise to always use new, disposable laboratory vessels and pipettes for all materials used in AMS experiments. This minimizes the potential for spread of contamination. For all experiments, control samples (predose or undosed) must be generated in order to provide a ^{14}C baseline for each experiment. Samples should be collected individually and sealed.

21.3.4.4 Sample Definition and Preparation. During the process of converting the sample material to graphite for AMS measurement, all chemical information contained in the original sample is lost. Thus, it is vitally important that the sample be adequately characterized before AMS analysis. This characterization will be specific for each type of sample and may in many cases be as simple as collecting and preparing a selected tissue or fluid (plasma, whole blood, urine, etc.). More complicated experiments may require additional separation and characterization techniques, including mass spectrometry, HPLC, flow cytometry, ELISA, isoelectric focusing, immunoblotting, or other analytical techniques, as needed to adequately separate and confirm the identity of the parent compound and metabolites.

It is essential to track all additions of carbon-containing compounds during the biological experiments and during sample preparation in order to produce meaningful data by AMS, since both total carbon and ^{14}C are measured to generate an isotope ratio. With some samples, it may be impossible to achieve the desired carbon amount from the experimental preparation. In this case, it may be necessary to add “carrier carbon” to these ultralow carbon mass samples. The primary source of carrier carbon now in use is tributyrin (glycerol tributanoate). This substance has the desirable characteristics of nonvolatility (bp $>300^\circ\text{C}$), high carbon content, and low ^{14}C content. A typical addition of carrier carbon occurs by adding 1 or $2\mu\text{l}$ of tributyrin in capillary tubes to the biological sample. It is always advisable to analyze each new type of sample for carbon content before graphitization to ensure that a proper carbon inventory is maintained.

21.3.4.5 Data Analysis and Interpretation. AMS reports result in Modern, which is a defined unit of $^{14}\text{C}/\text{C}$ isotope concentration equal to

- $1.180 \times 10^{-12} \text{ }^{14}\text{C}/\text{C}$,
- 13.56 mdpm/mg C,
- 226 $\mu\text{Bq}/\text{mg C}$, and
- 97.89 amol/mg C.

Conversion of this number to a meaningful result requires careful inventory of the carbon sources in the sample. For the simplest case in which a sample contains sufficient carbon as not to require the addition of carrier carbon, this conversion is facile. In many experiments, it is necessary to add carrier to make up the total amount of carbon necessary for the graphitization process to occur. In these experiments, the fraction Modern and the carbon mass of both the sample and the carrier must be considered in the calculation. Correctly accounting for all sources of carbon in the analyzed sample is essential, as a low estimate of carbon will artificially increase the apparent quantity of tracer, and an overestimate of carbon will deflate the apparent amount of tracer present.

The measured ratio is a composite value that includes the total amount of ^{14}C and the total carbon present in the measured sample. It is necessary to know the quantity of carbon and ^{14}C in the sample tissue, as well as the amount of carbon due to the tracer, in order to solve for the ^{14}C due to the tracer. If the only sources of carbon in the measured sample are the tracer and the tissue, determining the ^{14}C due to the tracer proceeds as follows:

$$R_{\text{Measured}} = \frac{{}^{14}\text{C}_{\text{Measured}}}{\text{C}_{\text{Measured}}} = \frac{{}^{14}\text{C}_{\text{tracer}} + {}^{14}\text{C}_{\text{tissue}}}{\text{C}_{\text{tracer}} + \text{C}_{\text{tissue}}} \quad (21.1)$$

In most cases, the carbon due to the tissue is much greater than the carbon due to the tracer, so that the tracer carbon can be neglected in the calculation:

$$R_{\text{Measured}} = \frac{{}^{14}\text{C}_{\text{tracer}} + {}^{14}\text{C}_{\text{tissue}}}{\text{C}_{\text{tissue}}} \quad (21.2)$$

Because the measured fraction Modern is a composite of the contribution of the tissue and the contribution of the tracer, rearranging to solve for the tracer ${}^{14}\text{C}$ gives

$${}^{14}\text{C}_{\text{tracer}} = \text{C}_{\text{tissue}} \times (R_{\text{measured}} - R_{\text{tissue}}) \quad (21.3)$$

where

$$R_{\text{tissue}} = \frac{{}^{14}\text{C}_{\text{tissue}}}{\text{C}_{\text{tissue}}} \quad (21.4)$$

If carrier carbon is also present, the general equation is as follows:

$$R_{\text{Measured}} = \frac{{}^{14}\text{C}_{\text{tracer}} + {}^{14}\text{C}_{\text{tissue}} + {}^{14}\text{C}_{\text{carrier}}}{\text{C}_{\text{tracer}} + \text{C}_{\text{tissue}} + \text{C}_{\text{carrier}}} \quad (21.5)$$

In this case, the carrier carbon is usually much greater than the carbon due to the tissue or the tracer, allowing these quantities to be neglected in the calculation:

$$R_{\text{Measured}} = \frac{{}^{14}\text{C}_{\text{tracer}} + {}^{14}\text{C}_{\text{tissue}} + {}^{14}\text{C}_{\text{carrier}}}{\text{C}_{\text{carrier}}} \quad (21.6)$$

which becomes

$${}^{14}\text{C}_{\text{tracer}} = \text{C}_{\text{carrier}} \times [R_{\text{measured}} - (R_{\text{tissue}} + R_{\text{carrier}})] \quad (21.7)$$

21.3.5 Specific Applications of Accelerator Mass Spectrometry

AMS excels at detecting very low levels of labeled compounds of interest and has been applied to a variety of types of experiments applicable to drug development. The common feature of these experiments is the ability to trace the fate of a labeled compound in a biological system. This can include determination of PK parameters, biotransformation of the labeled compound, formation of covalent adducts with cellular macromolecules, drug–ligand interactions, and tissue or subcellular localization of the compound of interest. Such experiments can provide valuable information about the pharmacological and toxicological characteristics of investigational compounds. AMS may likewise be used to investigate metabolism of endogenous, naturally occurring compounds within a biological system without perturbing the normal physiology of the system. The types of experiments listed below are by no means exhaustive but are intended to give the reader a sense of the potential value of AMS in the drug development process.

21.3.5.1 Pharmacokinetics. Several studies have compared the PK profiles of drugs using standard therapeutic doses and microdoses [14,21,26,31,45,51,67,68]. In these microdose experiments, a subtherapeutic level of a ^{14}C -labeled investigational compound is administered to animals or human volunteers, and the plasma levels of the compound are measured over time to determine the PK parameters of the compound. These experiments are essentially the same as traditional “dose and measure” PK experiments, but the investigational compound can be administered and measured at much lower levels than are possible using standard techniques. This allows for human studies to be performed without the risk of harmful effects that could occur with the administration of higher doses. While the utility of such microdosing experiments as a replacement for standard PK techniques remains a matter of discussion, several reports indicate that microdosing may be useful as a screening tool for drug candidates [14,21,26,67,69]. Microdosing may be particularly useful when a drug candidate presents with conflicting *in vitro* and animal PK data [67]. An understanding of the PK parameters of a drug candidate may disqualify the compound for further investigation based on a poor PK profile or may provide guidelines for predicting optimal doses within the therapeutic range. The plasma concentrations following oral and IV therapeutic (50 mg) and microdoses (100 μg) of sumatriptan are shown in Fig. 21.2 [26]. Despite the doses being different by a factor of 500, the dose normalized curves are very similar with the maximum plasma concentration occurring at about an hour. The biological half-life, volume of distribution, and clearance were all similar also [26]. The oral microdose had better bioavailability (20%) than the therapeutic dose (7.6%) [26].

In planning and conducting PK studies using AMS as a measurement technique, it is essential that an appropriate dose of the labeled material be administered to the test subject in order to allow accurate measurement at the selected time points. Assuming that the quantity of drug to be administered is significantly below the level required to elicit a pharmacological or toxic effect, dosing can be calculated based on the level of ^{14}C required to detect an adequate signal in the collected sample. If higher levels of drug are to be administered, the dose should be calculated based on the therapeutic dose

Figure 21.2 Semilog plots of mean plasma sumatriptan concentration–time profiles following a single oral dose of 100 μg ($\circ$), a 30-min IV infusion of 100 μg ($\square$), a single oral dose of 50 mg ($\blacklozenge$), and a 30-min IV infusion of 100 μg with a simultaneous oral dose of 50 mg ($\diamond$). Data are dose normalized to a 1-mg dose and error bars are ± 1 standard deviation. Source: (a) p. 144 from Lappin *et al.* [26].

range in addition to the radiological dose. The general steps involved in performing a PK study using AMS are as follows:

- Determine the specific activity of the ^{14}C -labeled compound of interest to be used in the PK study.
- Determine the mode(s) of administration of the compound of interest (injection, oral, dermal, subcutaneous, etc.). If appropriate, estimate the bioavailability of the compound.
- Determine the anticipated length of time the compound should be followed, the number of samples to be collected (blood and urine) and the sampling interval.
- Determine the minimum target fraction Modern to be achieved in the sample (blood and urine) at the final time point. In most cases, this level should be at least 10% above 1 Modern in order to allow appropriate resolution.
- Calculate the initial dose based on the estimated number of biological half-lives of the compound to produce the desired ending fraction Modern. Determine the total radiological exposure to be achieved using the calculated initial dose, assuming that the subject will absorb all radioactive decay energy. Consult with a health physicist to ensure that this level of exposure is acceptable based on current regulations and requirements. For purposes of assessing the radiological burden, a human can be assumed to have a normal ^{14}C level of 1 Modern, which for a 70-kg person corresponds to an energy deposit of 110 nJ/h, and assuming that the radiological dose is uniformly distributed throughout the body, this corresponds to 1.6 nSv/h [54].
- Use animal dosimetry data to initially estimate a compound's bioavailability and biological half-life, calculate the initial dose based on the target highest amount of label to be present in the sample, and proceed to calculate the total radiological exposure.
- The initial samples collected should be measured by LSC to ensure that the calculations were correct and that the level of dosing was correct for AMS measurement.

21.3.5.2 Biotransformation and Conjugate Formation. Identification of metabolites of a drug candidate or other molecule of interest can be greatly facilitated by AMS. Tracing of a ^{14}C label allows unequivocal identification of compounds originating from the ^{14}C -labeled parent compound, including metabolites and degradation products, even if the structures of these compounds are not previously known. This type of experiment may be performed by collecting blood and urine and separating components by HPLC or other separation techniques and identifying the parent compound as well as any metabolite or conjugate by measuring ^{14}C in the HPLC fractions.

Appropriate separation techniques are essential for the identification of metabolites. Although the presence of label introduced as the parent compound unambiguously demonstrates the source of the label, it is important to ensure that the collected material is reasonably pure to allow further characterization of novel metabolites. In many instances, the metabolites of a compound of interest may be unknown or incompletely characterized. A typical metabolism study consists of the following components:

- Characterize chemical purity, radiopurity, and specific activity of the ^{14}C -labeled compound of interest.

- Administer the labeled material and collect samples (blood, urine, tissue, etc.).
- Perform mass balance to account for all labeled material.
- Separate metabolites by standard techniques (HPLC, electrophoresis, etc.).
- Remove any solvents used in separations processes and analyze the sample fractions by AMS, adding carrier as necessary. In the case of HPLC fractions, the amount of carbon present in each sample is usually negligible compared to the amount of carrier carbon.
- Analysis occurs by comparison of cochromatography with authentic standards of detector peaks on the HPLC (e.g., UV) with AMS results to identify fractions containing the parent compound, its metabolites, and conjugates.

Glucuronide conjugation occurs with many drugs and it can be the single largest metabolite as shown in Fig. 21.3 [45]. Following a microdose of ^{14}C -acetaminophen, parent compound and major metabolites were separated by LC and fractions were analyzed by AMS [39]. In many studies, unexpected metabolites or conjugates are formed and labeled peaks elute at times different than the available standards [29,56]. Careful analysis of the elution spectrum can help narrow the possible metabolites. The ^{14}C signal clearly distinguishes the peak as deriving from the test compound and not an endogenous compound that happened to elute.

Figure 21.3 Time profiles of acetaminophen (AAP) and its metabolites in the pooled plasma of six subjects after oral administration of ^{14}C -AAP. Pooled plasma specimens collected at 0.25, 0.5, 1, 2, and 8 h were subjected to LC-AMS analysis. 3-*O*-Sul, AAP-3-hydroxysulfate; 4-*O*-Sul, AAP-4-hydroxysulfate; AAP, acetaminophen; Glu, AAP-glucuronide; LC-AMS, liquid chromatography–accelerator mass spectrometry. *Source*: p. 221 from Bauer *et al.* [85].

21.3.5.3 Protein and DNA Adduct Measurement for Determination of Reactive Metabolites. Incorporation of label into protein or DNA is a useful indicator of adduct formation or noncovalent binding of the moiety of interest. This approach has been used very successfully in the evaluation of known or potential carcinogens that exhibit DNA-binding activity [47,48,70,71]. This type of experiment may be particularly valuable in assessing the potential toxicity, mutagenicity, or carcinogenicity of a compound of interest. For example, AMS was used to detect DNA adducts in the colon after humans were exposed to a dietary-relevant dose of the cooked food carcinogen PhIP [47]. It may also be important to determine the quantitative fate of compounds that can form reactive intermediates capable of binding to cellular macromolecules, for example, compounds that can form immunogenic haptens or glutathione conjugates. Experiments of this type can also be designed to distinguish covalent and noncovalent interactions. As in the types of experiments described in previous sections, it is absolutely essential that the sample be thoroughly characterized and as pure as is reasonably achievable to ensure that results are not confounded by the presence of contaminating materials. These experiments include the following parameters:

- Determine the tissue to be sampled.
- Calculate the dose of compound to administer and the quantity of tissue to collect.
- Administer the dose and collect sample material.
- Separate and quantify the biomolecule of interest (protein and DNA).
- Perform AMS measurement on the sample.

21.3.5.4 Drug–Ligand Binding and Subcellular Localization. Tracing a radiolabel compound into tissues, cells, and even subcellular compartments is possible using AMS [69,72,73]. These experiments may be of great importance in determining the site of action and specific molecular target(s) of a drug or other compound of interest. Identifying the site of action or the molecular target of a drug candidate is very important in characterizing its biological activity and elucidating its mechanism of action. Such experiments could be a valuable screening tool to help in the selection of lead compounds for development as investigational drugs or to indicate that a compound has undesirable binding or localization characteristics early in the drug development process. As with other types of experiments, the sample material must be thoroughly characterized before AMS analysis. The steps involved in these types of experiments are similar to those described in the previous section but may include cellular fractionation in addition to isolation of target biomolecules.

21.4 LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY IN MICRODOSING

21.4.1 Overview of Liquid Chromatography-Mass Spectrometry

In addition to AMS, liquid chromatography-mass spectrometry (LC-MS) is also used to analyze samples in microdosing studies. Each method provides advantages but also has limitations. The previous section of this chapter described in detail the use of

AMS for microdosing experiments. This section describes the use of LC-MS/MS in microdosing studies, highlighting its advantages and disadvantages compared to AMS.

All microdosing experiments require analytical methods capable of identifying and quantifying the analyte(s) of interest in biological samples at low levels. In some cases, it may only be necessary to measure the administered (parent) compound. More often, the parent compound forms one or more metabolites that must be characterized and measured. Metabolites of interest may be formed at low concentrations relative to the parent compound. This can present significant analytical challenges in microdosing studies, because the parent compound is administered at low doses that may already be near the lower limit of quantitation (LLOQ) for most instruments. Thus, a method that is suitable for measurement of a parent compound in a microdosing study may not provide adequate sensitivity to measure low abundance metabolites, particularly those metabolites with uncharacterized structures [74]. AMS provides unrivaled sensitivity for measurement of ^{14}C -labeled compounds in biological samples and can detect labeled metabolites in an LC elution with *a priori* knowledge, but it provides only quantitation. Samples measured by AMS must be structurally characterized using other analytical methods. In contrast, LC-MS can identify compounds of interest, and can quantify material, but lacks the sensitivity of AMS. The specific questions that need to be answered, and the level of sensitivity required to answer those questions, must guide the researcher's choice of analytical methods to be used in microdosing studies.

21.4.2 Advantages and Limitations of Liquid Chromatography-Mass Spectrometry

Some general considerations can be applied in selecting the appropriate analytical methods for use in microdosing experiments. These considerations include types of instrumentation available and the capabilities of each instrument, the level of sensitivity needed, analytical methods that must be developed to enable microdosing studies, dosing considerations, and cost of performing microdosing studies. It should be noted that many studies have used both LC-MS and AMS to obtain the desired information.

21.4.2.1 Instrumentation. Many research facilities have LC-MS equipment, while very few have AMS instruments in-house. Both types of instrumentation require skilled and knowledgeable operators, and each instrument requires a specific type of sample preparation. AMS instruments measure samples in the form of graphite or CO_2 gas, while LC-MS instruments measure samples that are injected into the instrument in liquid form. Methods for preanalysis sample cleanup and processing will depend on the needs of the particular experiment being performed. In addition to providing quantitative information, LC-MS allows molecular characterization of parent drug and metabolites. Unlike LC-MS, AMS requires the use of a ^{14}C -labeled test compound and gives results in the form of an isotope ratio. AMS provides quantitation and requires that analytes be separated and characterized by other means before AMS analysis. AMS measures analytes that contain the ^{14}C label irrespective of their chemical structures, which can result in measurement of both parent compound and metabolites if adequate separation of these compounds is performed before AMS analysis. LC-MS can distinguish between a parent compound and its known metabolites with different m/z ratios but may not be sufficiently sensitive to detect low abundance metabolites.

Through chromatographic retention time and MS/MS, an observed m/z can be compared to a reference standard of the parent. LC-MS cannot resolve endogenous isobaric interferences, however, so discovering and identifying unexpected metabolites is very difficult. In detecting metabolites by LC-MS, it is helpful for the researcher to know what types of metabolites are likely to occur in order to optimize instrument parameters for the measurement of each metabolite.

21.4.2.2 Sensitivity. The typical analyte concentration range for LC-MS instruments is in the order of nanograms per milliliter sample [74–76], although some instruments can measure analytes in the picogram to femtogram per milliliter range [76,77]. In contrast, AMS instruments provide the highest level of sensitivity currently available and can measure from analytes in the range of femtograms to attograms per milliliter [74,75,78]. While AMS allows greater sensitivity than any other available methods, it is also extremely sensitive to minute quantities of contaminating material, necessitating great care in performing experiments and handling samples. Depending on the design of the study, the utility of AMS may be limited by the fact that all sources of ^{14}C label are measured, so that both the parent compound and the metabolites are measured [77]. Thus, caution must be exercised in interpreting the results of those microdosing studies in which parent compound and metabolites are not adequately separated and characterized. This problem can often be circumvented by the use of HPLC separation of the parent drug and its metabolites, followed by AMS analysis of each collected fraction. However, collection of HPLC fractions can be problematic due to the possibility of peak overlap [77].

21.4.2.3 Analytical Method Development and Sample Preparation. Both AMS and LC-MS methods typically require methods for extracting the test compound or its metabolites from a biological matrix such as plasma or urine. AMS has the advantage of being able to detect and quantify the ^{14}C -labeled test compound in the biological matrix without extraction if quantitation is all that is desired. AMS analysis does not require the use of internal standards or the generation of standard curves for the analyte(s). LC-MS requires the development and validation of an analytical method with a known linear range and lower limit of detection for each analyte and makes use of internal standards for analyte quantitation. MS can be linked directly to chromatography, unlike AMS, thereby mitigating concerns about loss of material as could occur in pre-AMS chromatography and fraction collection. Both AMS and LC-MS may require considerable sample processing before analysis. For AMS analysis, the possibility of contaminating samples with ^{14}C from other sources must be minimized.

21.4.2.4 Dosing Considerations. While both LC-MS and AMS microdosing studies involve the administration of small quantities of a substance to test substance, the test compound in AMS experiments contains a ^{14}C label, which presents extra challenges to ensure that the label is in a structurally stable position. The additional sensitivity provided by the use of a radioisotope-labeled test compound can enable detection of low abundance metabolites, as discussed above, and can allow more frequent sampling than would be possible if LC-MS detection was used. The ability to measure very low levels of analyte by AMS can also enable experiments of greater duration than is possible with LC-MS-based experiments. Conversely, the potentially long washout time for ^{14}C -labeled test compounds may limit the use of multiple dosing experiments or crossover studies.

21.4.2.5 Cost. In addition to the direct sample analysis costs, the time required to prepare test material, design and perform experiments, and complete analyses affects the total cost of microdosing studies. In-house equipment can speed up experiments and give results in a shorter time frame than is typically possible with AMS experiments. The high sensitivity that can be achieved by AMS requires a ^{14}C -labeled test compound, which increases the cost and time necessary to complete microdosing experiments. Additionally, AMS analysis following HPLC separation and fraction collection is limited by the relatively low throughput of this technique. AMS-based microdosing experiments are inherently more expensive than LC-MS-based experiments, but AMS can provide significant advantages that offset the additional costs. In some cases, AMS is the only analytical method available that has the sensitivity to provide the needed information.

21.4.3 Examples of Liquid Chromatography-Mass Spectrometry Microdosing

The ability to simultaneously identify and quantify a circulating drug or metabolite has made LC-MS microdosing an attractive alternative to AMS-based microdosing experiments. While not all drugs are suitable for LC-MS microdosing studies, several proof-of-principle experiments have been performed to demonstrate that LC-MS microdosing can be a viable method. The continuous improvements in instrument sensitivity made in recent years have enabled detection and quantitation of compounds at levels that were not previously possible. While quantitation by mass spectrometry is inherently problematic, it may be adequate in many cases to answer the critical questions in microdosing studies.

Ni *et al.* [68] investigated the utility of microdosing using LC-MS/MS by measuring rat plasma and urine metabolites using the drugs atorvastatin, ofloxacin, omeprazole, and tamoxifen with administered doses ranging from $1.67\text{ }\mu\text{g/kg}$ (microdose) to $5000\text{ }\mu\text{g/kg}$ (standard dose). Their analytical instrumentation included a 5500 QTRAP SYSTEM (AB Sciex, Concord, ON, Canada), with chromatographic separation on either a Shimadzu Prominence instrument (Columbia, MD) or an Agilent 1200 system (Palo Alto, CA). Quantitation was obtained using Analyst software (version 1.5, AB Sciex, Concord, ON, Canada), and metabolites were identified using LightSight software, version 2.2 (AB SCIEX). In the microdosing experiments, the researchers were able to characterize the hydroxylation metabolite of omeprazole, the hydration metabolite of tamoxifen, and the glucuronide metabolite of ofloxacin, while additional metabolites were identified at higher doses. These researchers reported that low dose PK parameters were not necessarily predictive of PK parameters at higher doses in the rodent model [74]. Similar experiments using additional drugs provided further support for the use of LC-MS/MS for microdosing experiments [79].

Yamane *et al.* [80] used LC-MS/MS to measure nicarbidine in humans and developed a method capable of measuring in the linear range of $1\text{--}500\text{ pg/mL}$ for a microdose and up to $0.2\text{--}100\text{ ng/mL}$ plasma for a clinical dose. This experiment used a microdose of $100\text{ }\mu\text{g}$ per patient and a clinical dose of 20 mg . They used mass spectrometry to identify metabolites following the microdose and compared these results with the metabolites identified using the clinical dose [80]. Yamazaki *et al.* [81] performed microdose studies in eight humans with $100\text{ }\mu\text{g}$ of fexofenadine and found that microdose PK measured using LC-MS predicted the PK of a 60-mg therapeutic dose satisfactorily.

Balani *et al.* [75] demonstrated that useful PK data could be obtained for the drugs fluconazole and tolbutamide using a microdose of 1 $\mu\text{g/kg}$ in rats and compared the linearity of PK with oral doses of 0.002, 0.01, 0.1, and 1 mg/kg of tolbutamide or 0.005, 0.05, and 5 mg/kg of fluconazole. Using LC-MS analysis, they reported 0.1 nM as the LLOQ for fluconazole and 1 nM as the LLOQ for tolbutamide. On the basis of adequate detection of test compounds by LC-MS and linear PK between microdoses and higher doses for both drugs, it was suggested that LC-MS/MS could provide adequate sensitivity for some human microdosing studies [75].

21.4.4 Summary

The decision to use LC-MS/MS or AMS must be informed by knowledge of the advantages and limitations of each method and primarily by the questions the microdosing study need to address. For further guidance in designing microdosing experiments, the interested reader is referred to the excellent review by Ings [77]. As the development of mass spectrometers with improved sensitivity continues, LC-MS is likely to find additional applications in microdosing experiments, but AMS is expected to remain the method of choice for many microdosing applications requiring high sensitivity.

21.5 POSITRON EMISSION TOMOGRAPHY IN MICRODOSING

21.5.1 Overview of Positron Emission Tomography

PET is widely used in medical imaging applications. In PET, a radioisotope that decays by positron emission is used to determine the location of the isotope in the test subject. Positrons react with electrons in tissue to annihilate each other and release two 511-keV photons at 180° from each other. An array of photon detectors located around the subject measure the simultaneous photons, and computers are used to reconstruct the position of the decay within the tissue with spatial resolution of $\sim 4\text{ mm}$ [22,82]. In microdosing applications, PET can be used to monitor distribution and clearance of a test compound in real time.

Positron-emitting radioisotopes need to be produced with a cyclotron and are short lived. The common positron-emitting isotopes for microdosing studies are ^{11}C (radioactive half-life $T_{1/2} = 20\text{ min}$) and ^{18}F ($T_{1/2} = 110\text{ min}$). ^{11}C is most useful since nearly all drugs contain carbon. Because of the short radioactive half-lives, cyclotrons must be located at medical facilities. After production of ^{11}C , it is typically exchanged with ^{12}C in a drug molecule in high activity radiochemistry facility also on-site to produce specific compounds that can be distributed and traced. The short radioactive half-lives require that the chemistry is rapid, and significant shielding is needed to protect chemists synthesizing the compounds. Finally, a PET scanner must be available on-site to measure the photons produced by positron–electron annihilation. After seven radioactive half-lives, an isotope decays to about 0.7% of its initial activity and is usually too weak for useful tracing. For ^{11}C , this is only 2.5 h, limiting PET analyses to initial distribution and rapidly clearing compounds. Since PET depends on the radioactive decay for measurement, it delivers a low to moderate radiation dose to test subjects. PET studies generally describe a normalized tissue deposition of a compound using standardized uptake values (SUVs). SUVs normalize the accumulated compound

in a tissue as measured by PET to the body weight of the subject and the injected dose [83]. Traditional PK parameters can be measured shortly after administration of the labeled tracer before its activity drops below quantitation limits.

21.5.2 Examples of Positron Emission Tomography Microdosing Studies

The advantage of PET over AMS and LC-MS is real-time visualization of distribution and concentration of the test compound in all tissues. PET can provide some PK information, but the rapid decay of the radioisotopes can only assess rapidly cleared compounds and metabolites. In general, PET is ill suited for metabolite analysis because of the time required for analysis and the low levels of compound in the small samples analyzed. The development of robust ultra performance liquid chromatography (UPLC) systems in the past few years with much shorter elution than traditional HPLC system may make PK of positron-emitting isotopes more practical. PET does not provide precise quantitation like AMS or structural information like LC-MS, it tells you if the test compound is concentrating in a particular tissue. The *in vivo* visualization is particularly useful when targeting a specific tissue such as CNS or diseased tissue such as cancer [84].

21.5.2.1 Tracing Across the Blood–Brain Barrier. PET has been used on several occasions to monitor the transport of a compound across the blood–brain barrier (BBB). A microdose study was conducted with the ^{11}C -labeled antiamyloid drug (ST1859) in healthy and patients afflicted with Alzheimer’s disease (AD) [85]. The test compound crossed the BBB relatively quickly and slows to washout in both control and AD groups, good qualities for a compound targeted at amyloid plaques. The study was not designed for detecting differences in the control and AD groups, but it appeared as though differences were present (Fig. 21.4). The AD group had an earlier maximum concentration in most brain regions and higher radioactivity in the brain than the control, suggesting differences in the BBB of the two groups [85].

A comparison of therapeutic dose (80 mg) and microdose (0.05 mg) of verapamil labeled with both ^{11}C and ^{14}C for PET and AMS analyses was conducted to investigate linearity [21]. PET measured similar rate constants across the BBB and distributed volumes for each dose [21]. ^{14}C concentration–time profiles in plasma were also similar for each dose [21]. A much earlier study with [^{11}C]raclopride saw similar cerebellum to blood concentrations with a microdose (1–2 μg) and a pharmacological dose (200–400 μg) [86].

21.5.2.2 Targeting Cancer. The development of new cancer drugs depends on identifying markers of the cancer and concentrating the drug at a tumor site compared to systemic circulation. PET is ideally suited for assessing drug distribution *in vivo* and determining if a cancer drug does indeed target the tumor preferentially compared to healthy tissue. PET microdosing offers the potential to obtain PK parameters in individual patients before commencing a therapeutic dose regimen or a noninvasive way to assess response or stage of a tumor with specific markers [84,87].

Although not strictly a microdose application, small doses of 16α - ^{18}F -fluoro-17 β -estradiol (FES) have been used to assess estrogen receptor (ER) status [88]. ER status of breast cancer can be assessed *in vivo* because FES is a ligand for ER [88]. Additionally, ^{11}C -colchicine has been used in preclinical PET studies to image multidrug resistance

Figure 21.4 Transaxial magnetic resonance–coregistered positron emission tomography (PET) summation images recorded from 20 to 90 min after intravenous injection of [^{11}C]ST1859 into 1 control subject (HV 1) (left) and 1 AD patient (patient 9) (right). The lower row shows the same PET images with the transparency of the superimposed magnetic resonance scan set to 50%. The radioactivity concentration is normalized for injected radioactivity per body weight and expressed as the SUV. *Source:* p. 829 from Tozuka *et al.* [45]. (See color insert.)

and identify tumors that will not respond to some chemotherapy agents [89]. ^{18}F -Fluoride has also been used for bone imaging [90].

An early pre-phase I study that used one-thousandth of the phase I starting dose of ^{11}C -N-[2-(dimethylamino)ethyl]acridine-4-carboxamide showed tissue distribution, tumor concentration, and early time point PK data were the first microdose PET study [91]. Combining PET with microdialysis to assess unbound drug in extracellular spaces has been done and may become more common in the future [92].

21.5.3 Summary

PET provides unparalleled *in vivo* distribution information with very low chemical doses. The short radioactive half-lives of positron emitters prevent acquisition of PK information in many cases.

21.6 CONCLUSION

Each bioanalytical technique employed in microdosing studies has its strengths and weaknesses (Table 21.2). LC-MS/MS is the least expensive and most widely available of the techniques. In most cases, if LC-MS/MS has the sensitivity to measure the test compound accurately, it is the preferred method. LC-MS/MS requires *a priori* knowledge of metabolites, however, and cannot definitively distinguish test compound from other molecules. AMS is most quantitative of the techniques. It is expensive to use and relatively few facilities are in operation. PET is at best semiquantitative, but

TABLE 21.2 Comparison of Bioanalytical Methods Suitable for Microdosing Studies

Attribute	AMS	LC-MS/MS	PET
Sensitivity limit (g)	10^{-18}	10^{-12}	10^{-14}
Linear range	Five to six orders of magnitude	Three to four orders of magnitude	Three to four orders of magnitude
Sample matrix measured	Plasma PK only	Plasma PK only	Plasma and tissue PK
Tissues sampled	Blood, urine, skin, saliva, exhaled CO ₂ , cerebrospinal fluid, feces, biopsy when available	Blood, urine, skin, saliva, cerebrospinal fluid, feces, biopsy when available	Tissues imaged, no sampling required
Radiation dose	Very low, generally microsievert	None	Low to moderate, millisievert
Radiolabel required	Long-lived β -emitter, ¹⁴ C	None	Short-lived β + emitter, ¹¹ C or ¹⁸ F
Chemical separation for metabolite analysis	Chemical separation of drug and metabolites possible. Metabolites quantifiable without analytical standards	Chemical separation of drug and metabolites possible. Structural information of metabolites possible. Metabolite quantification requires analytical standards	No chemical separation of tissue signal
Drug administration	Intravenous or oral usually, dermal and inhalation possible	Intravenous or oral usually, dermal and inhalation possible	Intravenous usually, oral or inhalation possible
Sampling periods	Limited by plasma clearance, minutes to months	Limited by plasma clearance and sensitivity, minutes to days	Limited by short half-life of positron emitters, up to 1.5 h
Costs	High cost, limited availability	Low cost, greater availability	High cost, limited availability
Outsource	Analysis can be contracted	Analysis can be contracted	Analysis must be done in-house

in vivo imaging allows analyses of distribution and accumulation of test compounds at target sites. Combining PET with LC-MS/MS or AMS provides the most information in a microdose study.

22.1 INTRODUCTION: FORMATION OF REACTIVE METABOLITE AND DRUG-INDUCED ADVERSE EFFECTS

Drug molecules are typically subject to biotransformation, that is, metabolism, once administered. Drug metabolism usually serves as a defense/detoxification mechanism, converting a drug molecule to hydrophilic metabolites, followed by removal of the latter from the circulation through urinary and/or biliary (via fecal) excretion [1,2]. However, drug metabolism sometimes becomes a process of “metabolic activation” or “bioactivation,” generating chemically reactive species such as α,β -unsaturated carbonyls, epoxides, isocyanates and isothiocyanates, quinones, quinone imines, and quinone methides. These metabolites are electrophiles capable of modifying proteins or nucleic acids, forming covalent chemical bonds with amino acid (e.g., cysteine, tyrosine, and lysine) residues or nucleoside base (e.g., adenine and guanine) components (Fig. 22.1a). The underlying mechanisms of these chemical reactions are often nucleophilic addition and substitution in nature. Structurally altered proteins and nucleic acids could lead to perturbed cellular functions, and consequently, drug-treatment-related AEs. Drug-metabolizing enzymes that catalyze the formation of reactive metabolites include cytochrome P450s (P450s), peroxidases, amine oxidase, and flavin-containing monooxygenase. Because these enzymes are proteins, they are sometimes prone to structural modification by reactive metabolites formed within their respective active sites, resulting in the so-called suicidal enzyme inactivation. For P450s, enzyme inactivation could also occur through heme alkylation or heme-iron

Figure 22.1 (a,b) Schematic representation of bioactivation and subsequent modification of proteins.

chelation. A covalently modified drug-metabolizing enzyme has the potential to cause drug treatment-related AEs not only by invoking a direct cytotoxic effect but also via drug-drug interactions due to diminished enzyme activity.

Parent drugs and their metabolites containing a carboxylic acid, alcohol, phenol, or amino functional group may undergo glucuronidation, sulfation, or acetylation. These biotransformation reactions occur in the presence of UDP-glucuronosyltransferases (UGT), sulfotransferases (SULTs), and *N*-acetyltransferases, respectively. Acyl glucuronides have been regarded as reactive species, in that they may acylate proteins through two different pathways, one of which is via displacement of the glucuronic

acid moiety by a cysteine, tyrosine, or lysine residue. The other mechanism involves migration of the aglycone at the pyranose ring, followed by scission of the hemiacetal ether bond to afford an aldehyde that reacts with a lysine residue to form an imine species, further intramolecular rearrangement of which yields a stable 1-amino-2-keto protein adduct (Fig. 22.1b). Acetylation and sulfation also mediate the formation of reactive metabolites, with acetate or sulfuric acid serving as a leaving group. The resulting cation species are capable of electrophilic addition to proteins or nucleic acids.

Drug molecules and metabolic products are eliminated from the circulation via biliary and/or urinary excretion, both of which in many cases are facilitated by active transporters such as bile salt export pump (BSEP), multidrug resistance-associated proteins (MRPs), and multidrug resistance proteins (MDRs). For those transporter substrates that are chemically reactive (e.g., acyl glucuronides or reversible GSH adducts), they could react directly with the transporter proteins or modify proteins/nucleic acids localized in a distal tissue compartment following migration assisted by transporters. Because active transporters serve to regulate the disposition of both xenobiotic (e.g., food, drug, and environmental chemicals) and endogenous substances (e.g., bile acids, cholesterol, and lipids), covalent modification of transporter proteins has the potential to disrupt transporter functions and produce drug treatment-related AEs resulting from excessive accumulation of cytotoxins.

Although circumstantial in nature, bioactivation appears particularly relevant to drug-induced hepatotoxicity on the basis that drug metabolism usually takes place in liver and reactive metabolites could readily alkylate/acylate hepatic proteins upon their formation *in situ*. This proposed scenario of liver injury is consistent with the observation that ~50% of clinical acute liver failure cases are likely drug treatment related [3]. In this context, mitochondria may either be a target or serve as a mediator for hepatotoxins, as the organelle not only produces ATP and other essentials to support cell survival but also regulates the programmed cell death process, namely, apoptosis. Insult from reactive metabolites would therefore start with structural modification of mitochondrial proteins and/or mitochondrial DNA (mtDNA), triggering pathogenesis such as inhibition of fatty acid oxidation, perturbation of cellular calcium homeostasis, oxidative stress, formation of peroxynitrite that induces membrane permeability transition, and collapse of mitochondrial membrane potential [4,5]. An alternative mechanism of drug-induced hepatotoxicity involves immune responses invoked by the formation of drug-protein adducts, which activate antigen-presenting Kupffer and Ito cells and produce T cells and antibodies that are cytotoxic to hepatocytes [6,7]. This type of liver injury usually exhibits a delayed onset of clinical symptoms on initial exposure to the offending drug. However, the AEs are to occur rapidly in response to rechallenge with either the implicated agent or a drug whose metabolism produces a structurally similar reactive species. Such a characteristic appears to represent a hallmark of immune-mediated AEs resulting from drug treatment. Injured hepatocytes undergo apoptosis if mitochondria remain functional and generate ATP. Necrotic cell death takes place when the damage to mitochondria is overwhelming and the organelles cease providing energy.

In addition to covalent modification of proteins and/or nucleic acids, reactive metabolites can form thioether or thioester with the cysteine residue of GSH (Fig. 22.2), a tripeptide consisting of L- γ -glutamyl-L-cysteinyl-glycine (Glu-Cys-Gly).

4 BIOACTIVATION AND REACTIVE METABOLITE ASSAYS

Figure 22.2 Structures of GSH and amino acid derivatives-related trapping agents.

This conjugation reaction may or may not require catalysis by glutathione-*S*-transferases (GSTs), depending on the chemical reactivity of the metabolites. The resulting GSH adducts are subject to hydrolysis of the tripeptide moiety, catalyzed by γ -glutamyltranspeptidase and dipeptidase. These hydrolytic reactions lead to the formation of cysteinylglycine and cysteine adducts, with the latter undergoing *N*-acetylation to afford the corresponding mercapturic acids [*N*-acetylcysteine (NAC) adducts]. Mercapturic acids usually are eliminated via urinary excretion. Although conjugation reactions with GSH generally represent detoxification, the thiol adducts sometimes serve as carriers for reactive metabolites, causing cellular damages in tissue compartments distal from the site where drug metabolism takes place. Possible scenarios include (i) retro-Michael reactions regenerating reactive species from which the GSH adducts are originated, (ii) further bioactivation of cysteine adducts via the β -lyase pathway, and (iii) exacerbation of tissue oxidative stress due to participation of thiol adducts in cellular redox cycling [8,9]. From a metabolite profiling perspective, identification of stable thiol adducts formed via the mercapturic acid pathway represents a bioanalytical option for the detection of reactive metabolites with short degradation half-lives in biological systems (see below).

22.2 DETECTION OF PEPTIDE AND PROTEIN ADDUCTS

Reactive species formed during drug metabolism processes usually are short lived, with their fate partitioning between reaction with biological molecules and further degradation to stable products. This has presented a technical challenge for direct detection

of reactive metabolites even with state-of-the-art instrumentation. An alternative is to identify derivatives resulting from reactions of the metabolites with the so-called trapping agents (Fig. 22.2). Such an approach has proved valuable during investigation of bioactivation mechanisms and identification of potential biological targets susceptible to covalent structural modification. In drug discovery and development settings, the data are utilized to construct an SAR aiding medicinal chemistry's effort to design and synthesize molecules with a low propensity to bioactivation.

22.2.1 Detection of GSH-Related Thiol Derivatives

Many reactive metabolites are electrophiles prone to react with nucleophilic amino acid residues of proteins, leading to the formation of covalently bound drug–protein adducts. One such amino acid is cysteine in its reduced form. Although the outcome can be very informative, analysis of protein adducts is relatively complex and resource consuming. In order to simplify bioanalytical procedures while not losing essential structural information, studies of bioactivation are often carried out via identification of the stable products resulting from nucleophilic “trapping” of electrophilic metabolites. For example, experiments are routinely performed to search for GSH adducts. The peptide GSH is an important endogenous substance, and one of its cellular functions is to scavenge reactive species (see above). GSH conjugation reactions also occur in incubations with liver microsomal or hepatocyte preparations when the thiol peptide is present. Detection of GSH adducts by MS is relatively straightforward due in part to the fact that MH^+ ions of those adducts produce characteristic fragments resulting from the neutral loss of 129 Da upon collision-induced dissociation (CID) [10]. A conventional approach is to analyze biological samples obtained from either *in vivo* or *in vitro* using the full scan functionality of an ion trap or triple quadrupole MS [11]. Initial identification of potential adducts is based on searching MH^+ ions corresponding to the combined molecular weights of GSH and the putative metabolites. Any molecular ion meeting the criteria is subject to CID, and further analysis focuses on the characteristic fragment ions such as those derived from the neutral losses of pyroglutamate (129 Da) and cysteine (75 Da). The probability of success for a full MS scan-based probe of GSH adducts is highly dependent on the experience of investigators when measured by the number of “false negative results.” An alternative is to use a neutral loss scan of 129 Da for detecting GSH adducts with triple quadrupole MS operated at positive ionization mode. Subsequently, the MH^+ ions identified are subject to CID, generating product ion spectra for structural analysis. One of the major limitations related to the neutral loss scan of 129 Da is its low sensitivity and selectivity; the former results from the inherited deficiency of full scan mode, while the latter is mainly due to interference by the biological matrix. This may be improved by scanning for those precursor ions $(M-H)^-$ that produce a specific fragment at m/z 272 with a triple quadrupole MS [12]. The ion of m/z 272 represents a diagnostic fragment of GSH adducts under the negative ionization mode, corresponding to the cleavage of the carbon–sulfur bond at the peptide moiety. Both the aforementioned approaches are relatively low throughput with application of “low” resolution MS (see below).

In order to improve sensitivity and selectivity, multiple reaction monitoring (MRM) has been used as an alternative to full scan for triggering the acquisition of enhanced product ion (EPI) spectra on a triple quadrupole linear ion trap MS, such as API4000 Q-Trap [13]. Thus, it was demonstrated that up to 114 MRM scans can be constructed

to monitor mass transitions resulting from the neutral losses of 129 and/or 307 Da, with the MH^+ ions proposed to target-specific GSH adducts whose structures are derived from a database of known bioactivation reactions including those observed for compounds with similar substructures. Detection of the desired signals by the MRM survey scan triggers a data-dependent acquisition of EPI, from which the structures of GSH adducts are deduced. As such, investigators should be able to obtain product ion spectra of targeted GSH adducts, and the sensitivity of detection could be as high as ~ 180 -fold better than the full-scan-based neutral loss survey scan. However, this approach would only enable identifying the GSH adducts “predicted” by a database based on which MRM survey scans are constructed. In other words, GSH adducts formed via “novel” bioactivation mechanisms are likely to escape from the detection.

Several derivatives of GSH have been synthesized for trapping reactive metabolites. One such agent is GSH ethyl ester (GSH-EE, Fig. 22.2) used *in vitro* to improve the sensitivity of detection [14]. The experiment was performed on a microbore liquid-chromatography-micro-electrospray-ionization tandem MS instrument. Detection of GSH-EE adducts was based on selected reaction monitoring (SRM) for simultaneously monitoring multiple MH^+ to $[MH-129]^+$ transitions, where $[MH-129]^+$ ions correspond to the neutral loss of pyroglutamate from the GSH-EE moiety. It appears that the sensitivity of detection was ~ 10 -fold better for GSH-EE adducts relative to GSH adducts. In a separate study, GSH and GSH-EE were added together into liver microsomal incubations in an attempt to increase the probability and certainty of identifying reactive metabolites by LC-MS analysis [15]. In this case, paired MH^+ ions with their mass difference of 28 Da were clearly indicative of GSH and GSH-EE adducts. Another GSH derivative synthesized for trapping purpose incorporated a quaternary 4-hydroxy-*N*-methylethyl piperidinium (QA-GSH, Fig. 22.2) [16]. Similar to GSH, QA-GSH “traps” electrophilic reactive metabolites, but detection of the resulting adducts by LC-MS was based on M^+ and $(M+H)^{2+}$ ions, as the agent already contains a fixed positive charge. Formation of QA-GSH adducts *in vitro* was semiquantifiable when the so-called QA-GSH standards were added during the sample processing and employed as internal standards for calibration purposes. Thus, the M^+ and $(M+H)^{2+}$ ions were monitored using either a multiple single reaction monitoring (mSRM) battery or a precursor ion scan of m/z 144, with the latter corresponding to the 4-hydroxy-*N*-methylethyl piperidinium ion liberated from QA-GSH adducts. Both GSH-EE and QA-GSH belong to a class of “artificial” trapping agents, and their trapping capability is dictated by chemical reactivity. For comparison, formation of GSH adducts in liver microsomal incubations sometimes can be enhanced via adding GST or hepatic cytosolic fraction [17]. A larger quantity of the metabolite formed should obviously improve the probability of detection. The experimental setup also better mimics the *in vivo* biological environment since GST is present in abundance in hepatocytes. Semiquantification is achievable in principle by employing a synthetic GSH adduct as an internal standard during LC-MS analysis.

The fragmentation of GSH adducts often is dominated by cleavages of the peptide bonds, and, as a result, the product ion spectra sometimes do not offer sufficient clues for structural analysis of drug portion of the adducts. Certain types of GSH adducts are chemically unstable, further complicating bioanalysis. An alternative trapping agent is NAc (Fig. 22.2) with a molecular weight of 163 Da. Unlike the corresponding GSH adducts, NAc adducts lack a peptide moiety and consequently their fragmentations are likely associated with drug portion of the molecules, hence more structural information

on the trapped reactive species and better understanding of the mechanism underlying bioactivation. In addition, NAc adducts can be detected *in vivo*, formation of which takes place via the mercapturic acid pathway following GSH conjugation reactions with reactive metabolites (see above). The conventional approach described above for detection of GSH adducts has also been employed for analysis of NAc adducts, such that identification of potential adducts focuses initially on searching MH^+ ions corresponding to the sum of 161 Da plus the molecular weights of putative reactive metabolites, followed by MS/MS analysis of the MH^+ ions in question. Similar to GSH adducts, NAc adducts produce fragments corresponding to the neutral loss of 129 Da, although the fragmentation is due to the cleavage of the thioether bond on the cysteine side of the molecule. On that basis, a neutral loss scan of 129 Da can be used for screening NAc adducts. In a recent report, NAc adducts formed either *in vitro* or *in vivo* were detected using a quadrupole linear ion trap MS with the polarity switching technique [18]. In the study, neutral loss scans of 129 Da, based on either full scan or MRM, triggered the acquisition of parent ion spectra and fragment-rich EPI spectra in a single LC-MS run for structural assignment. This method employs a generic data-acquisition protocol for detection of various NAc adducts and may therefore be suitable for fast screening of samples derived from *in vitro* and *in vivo* experiments. However, one of the limitations in such an approach is that it would only be able to identify those NAc adducts “predicted” by investigators. In addition, the neutral loss scan of 129 Da appears to exhibit lower sensitivity for detection of NAc adducts than for GSH adducts due likely to the fact that the two fragmentations are associated with cleavage of the chemical bonds with different strength. The thioether bond of an NAc adduct is much stronger than the peptide bond of a GSH adduct.

A recent development in instrumentation is related to the data acquisition with alternating low/high collision energy on high resolution MS (HRMS) such as a hybrid quadrupole time-of-flight (Q-TOF) MS. This improvement of methodology, in general, has increased not only bioanalytical throughput but also the sensitivity of detection for drug metabolites, including trapped reactive species [19,20]. The experimental setup starts with scans of ions at a low level of collision energy, followed by ramping collision energy to different levels in order to trigger CID. The first scan function at low collision energy detects the intact molecular ions, whereas the second scan at higher levels of collision energy generates MS^E spectra, where “E” represents collision energy. The MS^E spectra are equivalent to the ones obtained from nonselective tandem MS/MS scans, containing fragmentation information for the ions registered in the low collision energy scan [20]. However, MS^E spectra acquired by Q-TOF MS are not specific, as they lump together all fragments of the molecular ions that reach the detector at a given time. Such deficiency complicates the data interpretation but has been somewhat compensated by coupling HRMS with UPLC, which separates efficiently the analytes from each other as well as from the biological matrix [21]. Accurate mass-based postacquisition data processing software also aids interpretation of the MS^E spectra [22,23]. Consequently, a single sample injection onto UPLC-HRMS usually is sufficient to obtain both MS and MS^E spectra of the metabolites of interest. In this regard, detection of a diclofenac–GSH adduct may serve to demonstrate the utility of HRMS. Initial scans at low collision energy under the positive ionization mode of a sample from human liver microsomal incubations registered an MH^+ ion at m/z 583.1267, which corresponds to the exact mass of [diclofenac + GSH + O – Cl – H] (Fig. 22.3a). Subsequent automated switch to a scan at high collision energy

Figure 22.3 Detection by HRMS of a GSH adduct derived from diclofenac bioactivation.

produced an MS^E spectrum (Fig. 22.3b), followed by data processing of the spectrum by Metabolynx (Waters) for assignment of the fragment ions. The result supports the idea that diclofenac undergoes bioactivation to form reactive quinone imine or epoxide species, which are trapped by GSH conjugation reactions [24,25]. Similar to their counterpart with low mass resolution, HRMS also is equipped for searching GSH adducts via neutral loss scans [26]. In this case, consecutive pairs of low and high ionization energy spectra are generated for MH⁺ ions satisfying the neutral loss of 129.0426 Da within a window of ± 20 mDa. Once the instrument registers an MH⁺ ion with the specified neutral loss, it switches to MS/MS mode to collect an MS^E spectrum, providing sufficient information for subsequent structural analysis using data-processing software. The entire exercise often requires only a single sample injection, significantly enhancing the bioanalytical throughput. In principle, such an approach should be applicable for detection of not only GSH adducts but also drug metabolites with known characteristic neutral losses.

22.2.2 Detection of Amino acid- or Peptide-Related Adducts

Although GSH and NAc are the commonly used trapping agents, their utility to some extent is limited by their ability to form conjugates with reactive metabolites primarily via the sulfhydryl functional group. Some reactive species, such as quinones or quinone imines, may prefer to react with amines depending on their chemical reactivity, whereas certain thiol adducts could escape from detection by LC-MS analysis because they remain highly unstable and undergo degradation or rearrangement either in biological systems or during sample preparation [27,28]. In this context, individual amino acids or small synthetic peptides containing representative amino acid residues may serve as alternatives to GSH and NAc for trapping reactive metabolites formed *in vitro*.

It was therefore demonstrated that hydroxymethylvinyl ketone (HMVK) reacts readily with three model amino acids, namely, L-valinamide, *N*-acetyl-L-lysine (NAL), and NAc (Fig. 22.4) [29]. HMVK is a putative metabolite of 1,3-butadiene, which has been classified as a human carcinogen. Exposure to butadiene usually is associated with occupation and/or cigarette smoke. In the study, formation of adducts between HMVK and the model amino acids was monitored by HPLC with UV detection, while structural assignment was based on NMR analysis of purified products. Several HMVK-amino-acid adducts were identified, including those resulting from mono- and di-Michael addition(s) of the electrophile to the nucleophilic acceptors (Fig. 22.4). Among the amino acids tested, the reactive potential was in the order of NAc > valinamide > NAL, implying a free cysteine residue is a preferred site of modification. The detection of multiple different types of adducts has reinforced the idea that a variety of proteins are potential biological targets for HMVK *in vivo*. Similarly, cysteine, lysine, histidine, tyrosine, and serine were shown in a separate study to be able to trap quinone methides of different electrophilicity [30]. With HPLC-UV detection, three quinone methides, which were 4-methylene-2,5-cyclohexadienone derivatives, were observed to react rapidly with cysteine to form thioether derivatives with little or no competition from hydration in aqueous solutions. The α -amino groups of lysine, histidine, tyrosine, and serine were the primary sites of modification by the quinone methides, although alkylation also occurred with the side chain amino groups of lysine and histidine. The order of reactivity was cysteine thiol > N-terminal amine > *N* ϵ -lysine $\sim$ *N* Im-histidine, but this pattern of reactivity did not hold for peptides or proteins. For the

Figure 22.4 Structures of *in vitro* trapped adducts of HMVK with valinamide, NAL, and NAc.

synthetic tripeptide Gly-His-Lys and human hemoglobin, their primary sites of modification by the quinone methides were $N\alpha$ -glycine and $N\epsilon$ -lysine, respectively, based on LC-MS/MS analysis of the samples prepared with and without treatment by a protease.

Peptides may therefore represent better trapping agents when the focus of investigation is on the identity of modified amino acid residues. A generic experimental setup may include incubations of test compounds with human liver microsomes or recombinant P450s in the presence of a trapping peptide, followed by sample workup and LC-MS/MS analysis. For example, reduced oxytocin was employed as a model biological target of alkylation by the 2,4-diene derivative of valproic acid, an anti-convulsant agent that causes severe but rare liver injury [17]. Initial LC-MS scans registered an MH^+ ion of m/z 1491, consistent with a nucleophilic addition of two diene molecules to a single reduced oxytocin molecule. Subsequent CID of the MH^+ ion led to the assignment that the alkylation occurred at Cys-1 and Cys-6, suggesting that the sulfhydryl residues of proteins are vulnerable to attack following valproic acid bioactivation. Recent efforts include design and synthesis of trapping peptides that incorporate various nucleophilic amino acid residues in an attempt to capture different types of reactive species in a single experiment [31]. One such trapping agent was the 11-amino-acid peptide ECGHDRKAHYK containing not only cysteine but also other potential targets for nucleophilic addition/substitution, such as lysine and histidine. In incubation of a drug in question with the peptide in a bioactivation system, samples were partially purified and drug-peptide adducts retained on a cation-exchange chip

surface were analyzed by a surface-enhanced laser desorption ionization-time of flight (SELDI-TOF) MS. Identification of those adducts was based on parent ion scans for MH^+ corresponding to a combined mass of the trapping agent plus putative metabolites. Although application of an SELDI-TOF MS eliminated the requirement for separation by LC of the analytes, the instrument, in general, exhibits a relatively poor precision in comparison with conventional LC-MS and is incapable of generating fragmentation data to aid structural elucidation of the observed adducts as it lacks a CID function. Such an experimental setup was driven primarily by industrial research, characteristics of which include a rapid turnaround time to answer a much simplified question about bioactivation, that is, whether reactive metabolites are produced from a given test compound. Peptide-based trapping agents have the advantages of mimicking biological protein targets better than individual amino acids and providing information on the sites of modification. However, similar to GSH adducts, drug-peptide adducts usually offer insufficient or no information at all for the drug side of trapped products even if they are subjected to fragmentation. This can be very unsatisfactory for those whose research focus is on an SAR with respect to bioactivation. In this context, data from trapping experiments with GSH, NAc, and various peptides are likely complementary to each other.

22.2.3 Detection of Protein Adducts

Formation of protein adducts is at the center of a working hypothesis relating bioactivation to drug-induced AEs (see above). Identification of modified proteins should therefore represent a step forward to better understanding of the pathogenesis of tissue injury. When the modified protein is a drug-metabolizing enzyme, studies of the corresponding protein adduct not only bear toxicological significance but also shed light on interactions between the enzyme and its substrate, hence the relevant topography of enzyme active site. Similar to any analyte in question, detection of protein adducts usually begins with separation or partial purification of those adducts from biological matrix, and the techniques may fall into two major categories, one of which is one- and two-dimensional gel electrophoresis. An alternative is chromatographic separation, represented by HPLC and size exclusion, ion exchange, and affinity chromatographies. Popular means of detection includes immunochemical and MS analyses.

Immunochemical detection coupled with electrophoretic separation essentially constitutes the so-called Western blotting (see *Bioanalytics for Human Microdosing*), capable of identifying multiple modified proteins including the antigen(s) that may be responsible for causing pharmacotherapy-related hypersensitivity. Polyclonal antibodies are usually produced by immunization of laboratory animals, such as mice or rabbits, with a carrier protein conjugated to a drug or metabolite in question. Antibodies raised are present in serum, termed *antisera*, and can be used as is or subject to purification before application. Detection of protein adducts resulting from drug treatment is therefore based on recognition by the antisera or purified antibodies of the adducts separated by one- and two-dimensional gel electrophoresis. A classic example involves identification of acetaminophen (APAP)-related protein adducts, in which polyclonal antisera was obtained from rabbits immunized with APAP linked to keyhole limpet hemocyanin (KLH) via NAc [32]. After characterized for its specificity toward APAP-protein adducts by a competitive enzyme-linked immunosorbent assay (ELISA), the antisera was utilized for analysis of the serum samples collected from

patients administered with APAP. The results revealed that the subjects with increased serum transaminase levels had APAP–protein adducts in their circulations, whereas those without signs of liver injury did not exhibit immunochemically detectable signals for protein adducts. A reversed sequence of the aforementioned detection procedure is viable to determine if patients are “immunized” by drug treatment. For example, sera from patients who experienced tienilic acid-induced hepatitis recognized CYP2C9 protein but not other members in the CYP2C family on immunoblotting, suggesting the presence of anti-CYP2C9 antibodies in these patients [33]. Additional experiments with mutants of CYP2C9 identified three regions on the enzyme protein that form a binding pocket interacting with the antibodies. Similarly, antisera against proteins modified by halothane was present in patients who developed drug-treatment-related hepatotoxicity [34]. Detection of antibodies that recognize either native or modified proteins is of mechanistic importance, as it implicates an activated immune system in the pathogenesis of idiosyncratic drug toxicity (see above). In this regard, a patient treated by halothane several years earlier experienced desflurane-induced hepatotoxicity [35]. Subsequent analysis of serum samples from the patient by ELISA revealed that the sera exhibited reactivity toward liver microsomal proteins from rats treated with halothane. This led to the hypothesis that the patient was sensitized by the early halothane therapy and consequently became susceptible to desflurane treatment on the basis that metabolism of both halothane and desflurane generates putative trifluoroacetic chloride, a reactive species capable of binding covalently to proteins and, presumably, activating the immune system [35].

More recently, chromatographic separation coupled with MS detection has become a popular method for analysis of protein adducts. Advantages of an LC-MS/MS-based approach reside with not only sensitivity and accuracy but also a capacity of generating data for structural elucidation. In this context, LC-MS/MS analysis, together with the use of various types of proteases, often provides information on molecular weight of protein adducts and the amino acid residues modified. In one instance, such a method was used for detection of APAP–albumin adducts in patients administered with the analgesic [36]. An earlier experiment established that *N*-acetyl-*p*-benzoquinone imine (NAPQI) formed during APAP bioactivation reacts with the only Cys residue of serum albumin, and digestion of the protein adduct by pronase E gives rise to an NAPQI-Cys-Pro-Phe (NAPQI-CPF) adduct. Thus, serum specimens from three patients overdosed with APAP were analyzed by LC-MS/MS, following treatment of the samples with protease E. Serum from healthy volunteers served as controls. The tripeptide adduct was observed only in those who were ingested APAP, and its level was ~10-fold higher in a patient with severe hepatotoxicity. From the same samples, the LC-MS/MS assay also was able to pick up signals for the NAc and Cys adducts of NAPQI, providing additional data in a relatively straightforward analytical process that enables better understanding of the fate of NAPQI [36]. With respect to covalently modified drug-metabolizing enzyme, studies of the resulting protein adduct aid structural elucidation of the enzyme active site, complementary to the data collected by other techniques. For example, grapefruit juice intake can cause significant increases in systemic exposures of CYP3A substrate drugs such as cyclosporine and midazolam. Two major components in grapefruit juice, bergamottin (BG) and 6', 7'-dihydroxybergamottin (DHBG), were identified as irreversible inhibitors (inactivators) of CYP3A, possibly via modification of the enzyme apoprotein. Subsequent effort was focused on studies of the protein adducts formed during enzyme inactivation [37,38]. Recombinant or purified

enzymes were used in order to simplify bioanalysis. In one study, DHBG was incubated with purified CYP3A4, and the samples were injected sequentially onto two different HPLC columns for chromatographic separation of analytes from the matrix before MS analysis. Two protein adducts were detected, one of which exhibited the molecular ion corresponding to the intact CYP3A4 plus 386.8 Da, suggesting covalent binding of an oxygenated DHBG derivative to the enzyme apoprotein. The second adduct appeared to be a “bis-adduct,” with its molecular weight equal to the apoprotein modified by two oxygenated DHBG derivatives [37]. Similarly, a protein adduct detected in a separate study by LC-MS showed an increase of mass by 387 Da from the native enzyme when BG was incubated with purified CYP3A5, implying BG was converted to DHBG followed by protein alkylation [38]. A proposed mechanism has therefore attributed the loss of CYP3A activity in grapefruit juice drinkers to oxidation of the furan moiety of DHBG to an epoxide species that alkylates the enzyme apoprotein and consequently inactivates the enzyme. Detection of the bis-adduct resulting from interactions of DHBG with CYP3A4 implicates a large enzyme active site capable of accommodating more than one substrate molecule. Additional information concerning amino acid residues critical to enzyme activity may rely on studies of the peptides derived from digestion by proteases of the drug-protein adduct. One example involves raloxifene, which causes irreversible inhibition of CYP3A4. The loss of enzyme activity was attributed to alkylation by raloxifene of CYP3A4 apoprotein, as the inactivated enzyme maintains an intact heme-Fe moiety that produces spectrally detectable P450 similar to controls [39]. Further analysis by LC-MS/MS of inactivated CYP3A4 following digestion by protease K and trypsin, respectively, revealed that the Cys-239 and Tyr-75 residues were targets of alkylation by a reactive species, designated as extended quinone or diquinone methide, formed during raloxifene metabolism [40,41]. These data collectively suggest that Cys-239 and Tyr-75 are important to CYP3A4 activity.

22.2.4 Detection of DNA Adducts

DNA consists of deoxyguanylate, deoxyadenylate, deoxythymidylate, and deoxycytidylate, while purines and pyrimidines, including adenine, guanine, cytosine, uracil, and thymine, are the base units for constructing DNA molecules. Electrophilic reactive species formed during drug metabolism may react with the nucleophilic sites of purine and/or pyrimidine base units, causing covalent modification of, and lesions to, the nucleic acids. In response to the insult, cells activate repair enzymes or polymerases to identify and correct the damage in order to maintain normal cellular function. The affected cells undergo programmed cell death or mutation when damages overwhelm the repair mechanism, resulting in tissue injury or triggering cancer development. From a chemistry perspective, the nucleobase units of DNA molecules are “hard” nucleophiles that are susceptible to the attack by “hard” electrophiles (see below) such as epoxides, aldehydes, ketones, and quinones.

In this context, acetaldehyde (Fig. 22.5a), classified as a possible human carcinogen, is present in various foodstuffs and is an oxidative metabolite formed following alcohol consumption or cigarette smoking [42]. In an attempt to analyze DNA adducts resulting from exposures to acetaldehyde, calf thymus DNA was incubated with the suspected carcinogen, in the presence or absence of NaBH_3CN , and the resulting samples were hydrolyzed with aqueous HCl to release adenine- and guanine-related products for

Figure 22.5 *In vitro* reactions of acetaldehyde with calf thymus DNA (a) and styrene-7,8-oxide with salmon testis DNA (b).

analysis by LC-MS/MS with selective ion monitoring (SIM). N^2 -Ethylguanine (Et-Gua) or 1, N^2 -propanoguanine (Pr-Gua) was the major adduct, depending on whether incubations contained or lacked NaBH_3CN . Thus, the underlying mechanism likely involves the reaction of acetaldehyde with the DNA molecule, resulting in the formation of an unstable Schiff's base N^2 -ethylidineguanine adduct, chemical reduction of which by NaBH_3CN (followed by hydrolysis of the DNA adduct) produces Et-Gua. In the absence of the reducing agent, N^2 -ethylidineguanine undergoes further reaction with an additional molecule of acetaldehyde to give Pr-Gua (Fig. 22.5a). When acetaldehyde was incubated with cultured HL-60 cells, both Pr-Gua and Et-Gua were detected by LC-MS/MS, suggesting that alkylation of DNA by the aldehyde occurs in intact cells [42]. Covalent DNA modification also took place following incubations of calf thymus DNA with 5'-acetoxy- N' -nitrosomnicotine (5'-acetoxy-NNN), a precursor to the reactive species 5'-hydroxy-NNN resulting from tobacco smoking [43]. The reaction mixtures were subject to enzymatic hydrolysis by phosphodiesterase and alkaline phosphatase, and the adducts identified by LC-MS/MS with selected reaction monitoring (SRM) of $(\text{MH}^+ \rightarrow [\text{MH}-116]^+)$ mass transitions were pyridyloxobutyl-dGuo (POB-dGuo), POB-dCyt, and POB-Thd. The $[\text{MH}-116]^+$ fragment formed upon CID corresponds to the loss of the deoxyribose moiety from the nucleobase adduct MH^+ ion. Similar to aldehydes, epoxides, such as styrene-7,8-oxide, also are potential

mutagens and/or carcinogens. In incubations of styrene-7,8-oxide with salmon testis DNA, several adenine and guanine adducts were characterized by LC-MS/MS and UV detection following hydrolysis of modified DNA in aqueous HCl [44]. It appeared that alkylation at the N^7 of guanine accounted for 93% of total DNA modification (Fig. 22.5b), followed by 4% at the N^3 of adenine and the remaining 3% distributed among N^2 of guanine, C^1 of adenine, and N^6 of adenine. The N^7 of guanine has been perceived as a high reactivity center because of its nucleophilicity and accessibility, which is followed by the N^3 of adenine with similar nucleophilicity but slightly more steric hindrance [45]. Other positions on the nucleobase units can also become a main target of alkylation, depending on a specific electrophilic reactive species, as in the case of the reaction between acetaldehyde and DNA, where modification occurred primarily at the N^2 of guanine.

Detection of DNA adducts formed *in vivo* is likely most relevant to biological and pathological processes, and numerous studies have been conducted in laboratory animals. For example, acrylamide (AA, Fig. 22.6a) is a chemical with various applications

Figure 22.6 Formation of DNA adducts in mice dosed with acrylamide (a) and in rats dosed with MeIQx (b).

in industry, and its human exposures are associated with occupation as well as cigarette smoking and ingestion of fried starchy foods. AA is suspected to undergo bioactivation, getting converted to glycidamide (GA), which, being an epoxide, alkylates DNA [46]. Following a single dose from 1 to 50 mg/kg of AA to mice by intraperitoneal injection, liver, lung, and kidney were collected at 6 h for DNA extraction [47]. The resulting samples were subject to neutral thermal hydrolysis and partial purification by a size exclusion column. Two adducts, namely, N^7 -GA-Gua and N^3 -GA-Ade (Fig. 22.6a), were quantified by LC-MS/MS based on calibration curves generated with synthetic standards. The results revealed that formation of both adducts exhibited a dose-dependent response, with the level of N^7 -GA-Gua being ~ 100 -fold higher than that of N^3 -GA-Ade in rat tissues examined. Another example involves 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx, Fig. 22.6b), a structural representative of more than 20 heterocyclic aromatic amines formed during meat cooking. MeIQx is a rodent carcinogen and is considered as an agent of potential cancer risk to humans. Thus, MeIQx- C^8 -dG and MeIQx- N^2 -dG (Fig. 22.6b) were detected and quantified in liver samples from rats treated with MeIQx, based on LC-MS/MS SRM of $(MH^+ \rightarrow [MH-116]^+)$ mass transitions [48]. The observed higher level of MeIQx- N^2 -dG relative to that of MeIQx- C^8 -dG implies that the former adduct is likely an important contributor to MeIQx-induced genotoxicity in rodents. In a separate study, the neutral loss of deoxyribose was employed to trigger data-dependent acquisitions of the MS^3 product ion spectra [constant neutral loss (CNL)- MS^3 scan] for putative adducts [49]. In addition to MeIQx- N^2 -dG and MeIQx- C^8 -dG, an adenine adduct was identified via the CNL- MS^3 scan of liver samples from rats dosed with MeIQx. The structure of the adenine adduct was assigned as MeIQx- N^6 -dA according to the product ion spectrum. Most significantly, DNA adducts were also detected in humans, one of which is N^2 -ethylidene-dG derived from reactions of acetaldehyde with DNA (see above). In this case, DNA isolated from human lung and liver samples was subjected to hydrolysis in the presence of $NaBH_3CN$, converting chemically unstable N^2 -ethylidene-dG to the corresponding quantifiable N^2 -ethyl-dG [50]. Quantification of N^2 -ethyl-dG was based on LC-MS/MS SRM of $(MH^+ \rightarrow [MH-116]^+)$, using synthetic $[^{15}N]N$ -ethyl-dG as a stable isotope labeled internal standard. The results revealed an average of 0.1 adducts per million nucleotides in human livers and a similar level (0.13 per million nucleotides) in human lungs. There was no apparent difference between cigarette smokers and nonsmokers with respect to the level of N^2 -ethyl-dG in their lungs, although the comparison was confounded by a small number of subjects investigated ($n = 4$) and a significant period of hospitalization without cigarette smoking before the samples were collected [50]. Nevertheless, the ability to detect and quantify DNA adducts in patients is clearly very important toxicologically.

22.2.5 Detection of Adducts Trapped by Nonbiological Agents

Although GSH and NAc often serve as trapping agents, some compounds known to form reactive species causing covalent protein binding *in vivo* do not produce trapped adducts, which may be attributed to the instability of the adducts or the nature of reactive metabolites. In the latter instance, electrophiles and nucleophiles are generally grouped as “soft” or “hard” according to their chemical properties. Soft nucleophiles are large in size with diffuse charge, such as the thiol group of GSH, and react readily with soft electrophiles, for example, α,β -unsaturated keto group. Hard electrophiles

are small with intense charge and tend to react with hard nucleophiles. As a result, soft nucleophilic trapping agents may not be able to effectively trap hard electrophilic metabolites and vice versa, leading to a false assurance that bioactivation is absent. Therefore, there is a need to explore nonbiological chemicals as alternatives for trapping different types of reactive species.

Cyanide ion is one of the most commonly used supplemental agents for trapping reactive metabolites. It is a hard nucleophile and traps certain hard electrophiles (e.g., iminium ion) with which GSH and NAc may not react. Another advantage is that the resulting cyanide adducts are generally stable and readily identifiable by MS because of the facile loss of 27 Da (HCN) upon CID. For example, metabolism of 1-benzylpyrrolidine in rabbit liver microsomes leads to the formation of a pyrrolidinium ion, identification of which was based on detection by GC-MS of mono- and bis-cyano adducts (Fig. 22.7) when incubations were performed in the presence of sodium cyanide [51]. Formation of the pyrrolidinium was attributed to the observed covalent protein binding by 1-benzylpyrrolidine. Metabolism of [^3H]phencyclidine in rabbit liver microsomes, while generating an iminium species, also was associated with covalent protein binding [52]. The degree of covalent protein binding was reduced by 75% in incubations containing 0.1 mM sodium cyanide, suggesting that the reactive iminium ion is responsible for phencyclidine-related protein modification. It should be noted that sodium cyanide at high concentrations may inhibit drug-metabolizing enzymes, leading potentially to decreases in the formation of corresponding cyanide adduct [51]. Several studies revealed that an optimal concentration of sodium cyanide was 1 mM or less when used with rabbit or human liver microsomes [52,53].

In order to facilitate LC-MS/MS detection, a mixture of $\text{Na}^{13}\text{C}^{15}\text{N}$ with NaCN (1:1) has been exploited for trapping reactive metabolites [54]. The isotopic patterns of the corresponding cyanide adducts are characteristic and easily recognizable during LC-MS analysis. This approach not only is useful with nominal MS application but also enhances HRMS detection of adducts trapped by cyanide. In a recent report, cyanide adducts were detected by UPLC coupled with TOF MS in 8 of 12 tested compounds following incubations with human liver microsomes in the presence of 1 mM of a mixture of KCN and $\text{K}^{13}\text{C}^{15}\text{N}$ (1:1) [55]. The exercise further explored the use of the so-called mass defect filter for identification of the trapped adducts during data mining processes, and its success highlighted that a combination of HRMS and a stable-isotope-mixed CN trapping agent could significantly increase the throughput for screening reactive metabolites formed in an *in vitro* system.

Methoxyamine is a hard nucleophile prone to react with hard electrophilic aldehyde to form the corresponding oxime adducts [56]. DBOPN ([1*S*, 5*R*]-3-cyano-1-(3-furyl)-6-{6-[3-(3 *R*-hydroxy-6,8-dioxabicyclo[3.2.1]octanyl)]pyridine-2-yl-

Figure 22.7 Formation of mono- and bis-cyano adducts of 1-benzylpyrrolidine.

Figure 22.9 Formation of adducts of MRL-2 and MRL-3 with semicarbazide or GSH/NAc.

led to identification of five adducts by LC-MS/MS and NMR, four of which were derived from the mono- and bis-addition of methoxyamine to the oxidized furan moiety of DBOPN (Fig. 22.8a). Similar oxime adducts were also detected after incubating DBOPN with liver microsomes from dog, monkey, and human in the presence of hydroxylamine. Another example involves MRL-1, a furanopyridine derivative with a potential for anti-HIV treatment (Fig. 22.8b) [59]. MRL-1 caused covalent protein binding to rat, dog, monkey, and human liver microsomes in an NADPH-dependent manner, implying bioactivation and formation of reactive species. In liver microsomal incubations containing methoxyamine, metabolism of MRL-1 produced a ring-opened dihydrofurandiol tautomer that was trapped in the form of an *O*-methyloxime derivative (Fig. 22.8b). These two case studies clearly indicate that the furan ring represents a structural alert for bioactivation with the potential to form reactive epoxide and aldehyde derivatives in biological systems.

Semicarbazide is another small nucleophilic molecule capable of reacting with an aldehyde or ketone functional group to afford the corresponding stable semicarbazones. For example, two dipeptidyl peptidase-IV (DPP-IV) inhibitor analogs, MRL-2 and MRL-3 (Fig. 22.9), were subject to bioactivation in liver microsomes [60]. Covalent protein binding of the ³H-labeled MRL-2 and MRL-3 in rat liver microsomes was NADPH-dependent, suggesting P450-mediated bioactivation. Subsequent trapping experiments with GSH, NAc, and semicarbazide led to the identification of several adducts by LC-MS/MS analysis. A possible mechanism underlying the observed bioactivation involves hydroxylation at the C⁵ of the pyrrolidine moiety, with the resulting β -fluoroaldehyde partitioning between reaction with semicarbazide and elimination of HF. The latter process affords an α,β -unsaturated carbonyl that is trapped by conjugation reactions with GSH or NAc (Fig. 22.9). This case study highlights the value of different trapping agents in mechanistic studies of bioactivation.

22.3 SEMIQUANTITATIVE DETERMINATION OF BIOACTIVATION

Bioactivation of test compounds may involve phase I (e.g., epoxidation) and/or phase II reactions (e.g., acyl glucuronidation). If metabolism of the compounds in question is mainly through phase I reaction, incubations with liver microsomes are likely appropriate for evaluation of bioactivation. In cases where compounds undergo both

phase I and II metabolism, hepatocytes should be a better choice of *in vitro* systems for assessing bioactivation potentials. In general, radiolabeled tracers are required for quantifying covalent protein binding. ^{14}C -Labeled compounds are preferred from a chemical and metabolic stability perspective. On the other hand, ^3H tracers are often a suitable alternative to the corresponding ^{14}C tracers because the former are relatively easy to synthesize and possess higher specific radioactivity. However, the ^3H label may be lost if oxygenation of the test compound occurs directly at the carbon center where the ^3H label is attached. This can usually be tracked with appearance of $^3\text{H}_2\text{O}$ during sample analysis, and the data should be incorporated into the assessment of covalent protein binding. To quantify covalent protein binding is a resource-consuming exercise and has been a subject of other review articles [11,54].

Semiquantitative approaches employing radiolabeled trapping agents may become an attractive alternative to covalent protein binding analysis from a resource-saving perspective. For example, bioactivation of test compounds may be determined following trapping experiment using [^{35}S]cysteine and [^{14}C]sodium cyanide [61]. Four drugs, namely, clozapine, diclofenac, R-(+)-pulegone, and troglitazone, known to cause hepatotoxicity, were incubated in human liver microsomes in the presence of [^{35}S]cysteine or [^{14}C]sodium cyanide. The radioactive peak areas of the trapped [^{35}S]cysteine adducts exhibited a reasonable correlation with the extent of covalent protein binding determined via a conventional exhaustive wash method using radiolabeled test compounds. To include both [^{35}S]cysteine and [^{14}C]sodium cyanide in the trapping experiments enabled simultaneously trapping both soft and hard electrophilic reactive metabolites and therefore improved the accuracy of “predicting” the extent of covalent protein binding. In a separate study, a high throughput trapping assay incorporated the use of potassium [^{14}C]cyanide to assess the degree of bioactivation of unlabeled compounds in question [62]. These compounds were incubated with liver microsomes in the presence of [^{14}C]cyanide, and the resulting cyanide adducts were concentrated, while excess unreacted tracer was removed via solid-phase extraction. The cyanide adducts then were eluted from the solid-phase extraction columns and subject to liquid scintillation counting. The extent of bioactivation potential was estimated based on the amount of radiolabeled cyanide adducts derived from the test compounds. Such an approach can be useful for ranking compounds within the same structural class during drug discovery.

Dansyl glutathione (dGSH, Fig. 22.2) is a fluorescent-labeled GSH derivative, with a fluorescence tag attached to the GSH moiety [63]. Its advantage resides with the fact that while reactive species trapped by dGSH are characterized by LC-MS/MS analysis, the amount of dGSH adducts formed is quantifiable via the fluorescent detection. A different fluorescence-based assay was demonstrated to employ a GSH-embedded 96-well plate for high throughput screen of reactive species formed *in vitro* [64]. The 96-well plates are initially coated with poly(2-hydroxyethylmethacrylate) (pHEMA) polymeric membrane, followed by attachment of glutathione disulfate (GSSG) to the surface of pHEMA. The immobilized GSSG is reduced to GSH by treatment with DL-dithiothreitol (DTT) before use. Incubations of test compounds with liver microsomes are performed in the DTT-treated 96-well plate, and the resulting reactive metabolites are trapped via their reactions with GSH coated on the plate. Remaining unreacted GSH are “destroyed” by adding *N*-(iodoacetyl-amino-ethyl)-1-naphthylamine-5-sulfonic acid (1,5-I-AEDANS) at the end of each incubation, and the resulting GSH-1,5-AEDANS is quantified by a fluorescence measurement. The extent of GSH adducts formed in the

incubation is derived from a reciprocal relationship relative to the amount of GSH-1,5-AEDANS. This method provides a rapid semiquantitative assessment of bioactivation *in vitro* via P450-catalyzed pathway, while its limitations are associated with the preparation of GSSG-immobilized 96-well plates and low sensitivity of detection for the reactive species tested (e.g., 500 nM for NAPQI).

22.4 A GENERIC PROTOCOL FOR *IN VITRO* TRAPPING STUDY

Liver microsomal preparations are suspended in phosphate buffer (100 mM, pH 7.4) containing EDTA (1 mM), MgCl_2 (0.1 mM) with the final protein concentration of 1 mg protein/mL. A trapping agent dissolved in the phosphate buffer is added into the suspension with a final concentration of 5 mM for GSH or NAc, 1 mM for KCN/ $\text{K}^{13}\text{C}^{15}\text{N}$, or 1 mM for a DNA base. A test compound dissolved in methanol also is added to the suspension to give a final concentration of 10–50 μM . Incubations then are performed in the presence of 1.2 mM of NADPH at 37°C for 30–60 min. Reactions are terminated by adding 3 $\times$ of acetonitrile, and the mixture is sonicated for 5 min and centrifuged at 20,800g at 4°C for 10 min. The resulting supernatant is collected, while the protein pellet is extracted twice with 1 mL of aqueous methanol (75%, v/v). The extracts and the supernatant are combined and evaporated to dryness under nitrogen at room temperature. The residues are suspended in 300 μL of aqueous acetonitrile (66%, v/v), an aliquot (75 μL) of which is subjected to LC-MS/MS analysis [65]. Further details can be found in experimental protocols published previously [10,11].

22.5 DATA INTERPRETATION AND UTILIZATION

Identification of reactive metabolites and their protein/nucleic acid adducts has been a focus of academic research in the area of toxicology and will likely be a part of future investigations exploring the pathogenic process leading to clinical onset of toxicity. A clear mechanistic understanding should significantly improve the detection and subsequent treatment of various tissue injuries resulting from pharmacotherapy. Although a rare example, APAP–protein adducts quantified in the circulation have been shown to serve as a possible biomarker for hepatotoxicity in patients suspected of drug overdose [66]. An accurate and timely diagnosis in this case is critical, as treatment with NAc is most effective if the antidote is given within ~ 16 h of APAP administration. On the other hand, identification of GSH adducts and related metabolites formed via the mercapturic acid pathway may be of toxicological importance in addition to simply “trapping” reactive metabolites for bioanalysis. A number of thiol adducts are implicated as culprits in drug-induced AEs. For example, terbinafine metabolism generates 7,7-dimethylhept-2-ene-4-ynal, an allylic aldehyde that reacts readily with GSH via 1,6-Michael addition [67]. The resulting GSH adduct remains an electrophilic α,β -unsaturated carbonyl and also undergoes a retro-Michael reaction to convert back to the allylic aldehyde. These reactive species are suspected of covalently modifying MRP2 protein, leading to a compromised transporter activity and consequently drug-induced cholestasis. Alternatively, GSH adducts can undergo metabolism to form the corresponding cysteine adducts, which may be subject to bioactivation mediated by

renal β -lyase. The resulting reactive species are capable of modifying kidney proteins, causing nephrotoxicity such as that illustrated in patients exposed to haloalkenes [68].

From a pharmaceutical research perspective, one of the primary purposes of measuring bioactivation is to guide medicinal chemistry effort in drug discovery. There are numerous successful examples in terms of minimizing bioactivation during lead optimization processes [11]. Many of the scenarios reported usually involve the identification by LC-MS/MS of GSH adducts, followed by chemical intervention via incorporation of an electronegative functionality, such as F, CN, or heterocyclic moiety, into the structural series in order to reduce bioactivation potential. A few case studies also suggest that selection of a “meaningful” trapping agent should rely on the knowledge of specific toxicity. For example, MRL-4 (Fig. 22.10a) is a potent cGMP-dependent protein kinase inhibitor for prevention and/or treatment of coccidiosis, but the compound promoted mutation in Ames tests when assays were performed in the presence of rat liver S9 fraction. This observation indicates that mutagenic effect shown by MRL-4 was dependent on its bioactivation. Further studies of MRL-4 metabolism in incubations with rat liver S9 containing guanine or cyanide led to the identification by LC-MS/MS of two possible reactive species (Fig. 22.10a). The first was likely an iminium ion capable of reacting with both the trapping agents to afford *N*-cyanomethyl

Figure 22.10 Bioactivation of MRL-4 and MRL-5 and formation of CN and guanine adducts.

and *N*-guaninemethyl piperidine derivatives, respectively. The second reactive metabolite presumably was a nitrenium ion, formation of which could begin with oxidation of the aminopyrimidine moiety to yield an *N*-hydroxyarylamine, followed by dehydration or a loss of sulfate/glucuronic acid if sulfation/glucuronidation of the hydroxyamine took place. The putative nitrenium ion reacted only with guanine, producing a guanine adduct. Subsequently, MRL-5 (Fig. 22.10b) was synthesized, which retained the arylamine functionality but replaced the piperidine moiety with chlorine. The compound, when evaluated for mutagenic and bioactivation potential, was Ames positive and formed a guanine adduct in incubations with rat liver S9. Collectively, these data support the idea that bioactivation is responsible for the mutagenic effect of MRL-4 and related arylamine analogs, whereas guanine adducts in this case serve as a better indicator for the formation of “toxicity-relevant” reactive species. Further lead optimization efforts eliminated arylamine from the structural class and consequently produced compounds that were Ames negative.

This example highlights the importance of minimizing bioactivation, while at the same time emphasizes the significance of data interpretation in relation to the knowledge of toxicity in question. Metabolites with different chemical reactivity are likely to target different biological molecules, some of which are biologically/toxicologically important, but others may simply serve as “scavengers” of reactive species. Such a scenario represents a dilemma for decision making in drug discovery, where data interpretation in many cases is prospective rather than retrospective. A core issue is the level of confidence with which one could claim a drug candidate would or would not cause harm to the patient according to a metabolism/bioactivation data set. Although this is a complex question, it appears that daily dose load is an important factor in determining the risk level of a compound, presumably due to saturable detoxification pathways. An empirical analysis suggests that drugs with a daily dose at 10 mg or less are associated with low incidence of drug-induced AEs [69]. Several recent studies attempted to test the hypothesis on whether reactive metabolites are the culprits responsible for clinical drug toxicity. In one study, 37 compounds were divided into 3 classes according to their safety status, including safe drugs (no warnings), warnings for toxicities, and black box warning/withdrawn from the market [70]. Bioactivation was measured by covalent protein binding quantified in incubations with human liver microsomes. The result suggests that majority of the compounds (30 out of 37) evaluated could be placed into their designated safety categories when daily dose was factored into the data analysis. A separate investigation of 50 drug products also was able to discriminate “toxic” from “safe” agents, using a criterion that normalized the extent of GSH adducts formed in human liver microsomal incubations to the daily doses prescribed [71]. Additional aspects deserving careful consideration during the selection of drug candidates include therapeutic areas and patient populations. A decision then can be made to balance the benefit and risk in order to satisfy unmet medical needs.

Last but not least, it should be noted that bioactivation represents only one of the several possible mechanisms underlying drug-induced AEs. Compounds can be intrinsically cytotoxic or can form metabolites that are cytotoxins but not chemically reactive. One such example is ximelagatran, a direct thrombin inhibitor prescribed for anticoagulation. The drug was removed from the market following clinical observations that ximelagatran treatment was associated with a significant elevation of liver enzymes and thus a high risk of severe liver injury [72]. Subsequent attempts to connect the

clinical AE and ximelagatran metabolism failed to identify GSH adducts or detect covalent protein binding in incubations with human liver microsomes or hepatocytes [73]. A probable cause of ximelagatran-induced hepatotoxicity remains obscure, although some evidence implies that the observed liver enzyme increases on drug treatment is immune mediated and dependent on specific genotypes of the major histocompatibility complex [74]. The parent drug also directly affected the plasma membrane fluidity and lipid composition in human hepatocyte incubations [75]. Similarly, troglitazone could serve to demonstrate that sometimes there are multiple mechanistic explanations for a pharmacotherapy-related AE in question. The drug was an agonist of the peroxisome-proliferator-activated receptor in the thiazolidinedione structural class for treatment of diabetes. Troglitazone was withdrawn from the market following numerous clinical reports of severe liver injury characterized by hepatocyte necrosis and bile duct proliferation. Metabolism of the drug leads to the formation of several reactive species, most of which are derived from P450-catalyzed oxidation of the chromane and thiazolidinedione moieties [76,77]. While these metabolites in principle could initiate pathogenesis of liver injury, the parent drug itself exhibited cytotoxicity to HepG2 cells expressing limited P450 activity [78]. Troglitazone also was subject to extensive sulfation in patients; the resulting sulfate derivative was the most abundant circulating metabolite with its plasma concentrations several-fold higher than that of parent drug [79,80]. Both troglitazone and the sulfate metabolite exhibited strong inhibition of BSEP *in vitro*, and their IC₅₀ values and clinical exposures were within a similar concentration range. Because BSEP is a hepatic canalicular transporter regulating bile flow and removal of bile acids from liver, a compromised transporter function on drug treatment could lead to an accumulation of toxic bile acids in hepatocytes and subsequent cholestatic liver injury in susceptible patients. On that basis, inhibition of BSEP by troglitazone and its chemically inactive metabolite represents an alternative to bioactivation as a hypothesis to explain the drug-induced hepatotoxicity. Collectively, the above case studies suggest that clinical AEs, including liver injury, do not necessarily follow the path of forming reactive metabolites from the offending drug. With respect to pharmaceutical research, a balanced approach appears preferable such that the effort of minimizing bioactivation potential does not result in a delay of pivotal preclinical safety studies. It is conceivable that further clarification of the relationship between bioactivation and pharmacotherapy-related AEs should affect greatly the strategy of drug discovery and development, leading eventually to improved drug safety.

ACKNOWLEDGMENT

The authors thank Huifang Yao for providing the HRMS spectra of a GSH adduct resulting from diclofenac bioactivation.

Abstract

A number of small-molecule drugs that cause severe adverse effects (AEs) undergo metabolism to form reactive species capable of covalently modifying proteins and/or nucleic acids. This has led to a working hypothesis that eliminating compounds susceptible to bioactivation in drug discovery should eventually produce safer medicines. A technical challenge associated with this strategy is to identify reactive metabolites that are often short lived either in biological systems or during sample preparation. Current bioanalytical options include capture of reactive metabolites with various trapping agents, such as glutathione (GSH) derivatives, synthetic peptides, cyanide, and nucleobase derivatives. These agents “trap” different types of reactive species, presenting the first hint on the mechanism of bioactivation. *In vitro* incubations usually are carried out in the presence of an appropriate trapping agent, with liver microsomes or hepatocytes serving as the source of enzymes responsible for bioactivation. The resulting samples are subjected to chromatographic separations and mass spectrometry (MS)-based detection of the trapped stable products. Similar procedures are applicable to specimens from preclinical species and humans for identification of GSH-related adducts formed *in vivo* via the mercapturic acid pathway. Sample analyses by triple quadrupole or ion trap mass spectrometers follow primarily a stepwise manner from neutral loss and/or parent ion scans to multiple-stage mass fragmentations in order to acquire sufficient data for metabolite structural assignment. Recent developments in instrumentation have centered on coupling ultraperformance liquid chromatography (UPLC) and high resolution MS; this combination is able to achieve a superior separation of analytes and acquisition of accurate mass spectra, hence a significant increase in sample throughput and improvement of metabolite detection. Use of accurate mass-based data-processing software further simplifies data interpretation, enabling quick structural assignment of the trapped products from which reactive species and bioactivation mechanisms are deduced. From a bioanalytical perspective, these experiments often require minimal sample preparation and method development, with a throughput usually satisfying the need of medicinal chemistry to construct a structure–activity relationship (SAR) with respect to the formation of reactive metabolites. The database accumulated, together with preclinical and clinical safety information, should also lead to better understanding of drug treatment-related adverse effects (AEs).

23.1 SUMMARY

This chapter provides an overview of both conventional and unconventional methods to determine plasma protein binding. Plasma protein binding is an important ADME parameter required to understand drug efficacy and possibly toxicity. Plasma protein binding refers to the noncovalent interaction of drugs with plasma proteins such as albumin and α -acid glycoprotein (α -AGP). It may contribute to a wide variety of ADME phenomena such as drug–drug interaction potential and nonlinear, stereoselective, or interindividual pharmacokinetics variability. Therefore, the potential exists to identify and differentiate drug candidates based on plasma protein-binding values. Experiments using plasma protein binding advance our understanding of ADME properties to aid in candidate selection and development by determination of the unbound drug blood concentrations as well as (potentially) drug concentration at the site of action.

Recent progress in automation as well as increased routine performance of the analytical instrumentation has enabled a greater number of compounds to be assayed earlier in discovery, often at a high enough quality level such that repeat determinations later in development are not needed. Significant effort has been invested to search for high throughput screening methods that reliably and accurately determine protein binding in early drug discovery. The development of 96-well formats for equilibrium dialysis, ultrafiltration, and ultracentrifugation, combined with liquid handling automation have

transformed a formerly tedious, labor-intensive assay into a process, which can now be swiftly conducted. In addition, new approaches, referred to as *emerging techniques*, are also under investigation, including chromatographic methods such as the human serum albumin (HSA) column and spectroscopic methods such as surface plasma resonance, solid-phase microextraction, Transil membrane screening, and capillary electrophoresis (CE) methods.

Significant challenges still remain unsolved, particularly in cases of high protein binding with low exposure levels that fall below the normal limit of quantitation (LOQ). This chapter describes the impact of high (>99%), undeterminable protein binding on compound developability as well as possible solutions including plasma dilution techniques.

23.2 INTRODUCTION

The use of *in vitro* ADME (absorption, distribution, metabolism, and excretion) tools offers the exciting prospect of optimizing a drug candidate's efficacy while potentially reducing costly attrition during drug development. Over the last two decades, enormous investment and interest have blossomed in high throughput *in vitro* ADME screens, such as permeability, metabolic stability, drug–drug interaction potential, and transporter affinity. From a hierarchical perspective, *in vitro* methods of plasma protein binding for drug candidates have been less preferred and less frequently performed than other ADME screens. However, as the value of plasma-protein-binding data has become better understood, and, as more tools have been developed to conduct the experiment in a higher throughput manner, the conduct of plasma-protein-binding assays has increased in the early discovery or lead optimization space.

Plasma protein binding refers to the noncovalent interaction of drugs with plasma proteins such as albumin and α_1 -acid glycoprotein (α -AGP). The premise that only unbound or free drug is available to exert a pharmacological effect is known as the *free drug hypothesis* [1,2]. Although there is controversy in the literature, unbound drug levels are generally regarded to be the principal determinant of tissue distribution, cell entry, receptor interactions, and availability for elimination, thus impacting the pharmacokinetic/pharmacodynamic (PK/PD) relationship or off-target adverse reactions or toxicities. Plasma protein binding may contribute to a wide variety of ADME phenomena such as drug–drug interaction potential and nonlinear, stereoselective, or interindividual pharmacokinetics variability. Therefore, the potential exists to identify and differentiate drug candidates based on plasma-protein-binding values [3,4]. Plasma-protein-binding experiments advance our understanding of ADME properties to aid in candidate selection and development by determination of the unbound drug blood concentrations as well as (potentially) drug concentration at the site of action.

In 2002, the clinical relevance of plasma protein binding was challenged by Benet and Hoener [5], who through careful study demonstrated that protein binding is relevant primarily for IV administered drugs with a high extraction ratio and oral drugs with a high extraction ratio and a nonhepatic clearance mechanism. Examination of data for 456 currently marketed drugs showed that protein binding influenced exposure for 25, which fell into the two categories described above. If the therapeutic index is considered, protein binding influences even fewer compounds. Benet and Hoener's work might lead some to conclude that the protein-binding experiments are not worth

the time and effort they consume. However, the clear need for protein binding in the discovery and preclinical development stages to conduct allometric scaling and understand species-difference behavior is well understood. In rare cases, differences between animal and human plasma-protein-binding values may lead to significant differences in observed clearance, with severe negative outcomes. Protein-binding behavior of a drug candidate may not be in and of itself decision making, but has a profound influence on a variety of *in vivo* and *in vitro* properties during ADME and pharmacology experiments. Thus, its determination early in drug discovery can provide significant input into understanding tissue distribution and pharmacological effect.

Before the last decade, a significant stumbling block of plasma-protein-binding methods has been lack of miniaturization and automation. Plasma protein binding has been traditionally performed by equilibrium dialysis during drug development using ^3H - or ^{14}C -labeled compounds. The timing of these experiments is largely determined by the effort and expense to obtain radiolabeled material. The traditional methods consume a significant amount of material, are very labor intensive and not easily automated, but are considered sufficiently rigorous to permit data inclusion in regulatory submissions.

Significant effort has been invested to search for high throughput screening methods that reliably and accurately determine protein binding in early drug discovery. The development of 96-well formats for equilibrium dialysis and the coupling of this with liquid handling automation have transformed a formerly tedious, labor-intensive assay into a process that can now be swiftly conducted. However, as 96-well techniques are validated, the need for the final low throughput “definitive” radiometric experiment is becoming less and less compelling. In some situations, experimental results derived

Figure 23.1 Overview of plasma-protein-binding methods during drug discovery and development.

from LC/MS/MS analysis may be used in regulatory submissions. In addition, new approaches referred to as *emerging techniques* are also under investigation and they will be described later.

An overview of normal timings of the techniques, which will be discussed are shown in Fig. 23.1. Early in drug discovery, rapid screening techniques that allow binning into low, medium, and high binding categories may be utilized. As a potential drug candidate progresses forward in the drug discovery process, and more of it is synthesized, more definitive approaches such as equilibrium dialysis are applied. Once a drug candidate is deemed to have a high likelihood of success, traditional equilibrium dialysis using radiometric detection may be performed. However, the approaches used across the pharmaceutical industry continue to evolve. With significant recent improvements in the high throughput automated devices used to conduct the incubations as well as the analytical instrumentation, the need for the “definitive” radiometric experiment is declining. Some companies may also choose not to invest resources in the conduct of binning experiments if higher quality data can be obtained with appropriate turnaround time from the 96-well equilibrium dialysis, ultrafiltration, or ultracentrifugation experiments. The maturation of plasma-protein-binding assays continues to be both an interesting and dynamic process.

23.3 TRADITIONAL METHODS

Plasma protein binding has been conducted for several decades as part of normal compound progression from animal experiments into the clinic. The original manually conducted experiments relied on simple approaches utilizing common laboratory equipments such as the centrifuge. An overview of the experimental process for “traditional” techniques [6], based on their popularity and longevity of conduct, that is,

Figure 23.2 Process flow for traditional methods of plasma protein binding: ultrafiltration, ultracentrifugation, and equilibrium dialysis.

ultrafiltration, equilibrium dialysis, and ultracentrifugation is shown in Fig. 23.2. In addition, a summary of the advantages and issues, as well as, comparison with more innovative or higher throughput approaches described later in this chapter, is shown in Table 23.1.

When embarking on a protein-binding assay, several variables should be considered in the experimental design. The choice of which preclinical species to examine should be dictated by the purpose of the protein-binding experiments, such as PK calculations, PK/PD relationship, or exposure margin calculations for safety assessment studies. Plasma protein binding should be evaluated over an anticipated therapeutically and/or toxicologically relevant concentration range for the compound of interest. Additionally, these methods can be used to investigate individual binding proteins (i.e., HSA, α -AGP, preclinical species' albumin). Plasma harvested using EDTA as an anticoagulant is recommended. Concerns have been raised that the anticoagulant heparin may interfere with protein binding, and it should thus be avoided. During preparation of initial analyte-spiked plasma, minimal organic content (<2% by volume) should be maintained to minimize interference with protein binding. The stability of the compound in all species and matrices, including buffer solutions, should be assessed over the time period used for equilibration. This is accomplished by incubating an aliquot of the matrix standard and spiked buffer at the lowest concentration under the same conditions as the equilibrium dialysis apparatus. Samples taken at time zero and at the end of experiment should be assessed to determine percentage of analyte remaining.

23.3.1 Ultrafiltration

Ultrafiltration experiments [7–10] have been conducted in 96-well format for over a decade, thanks to the commercial availability of the filtration plates. In this experiment, an aliquot of analyte-spiked plasma is pipetted into an individual well of a single-use 96-well device. The bottom of this well is composed of a filtration membrane with a 10,000 Da molecular weight cutoff. The entire device is then centrifuged, during which time the unbound analyte solvated in plasma water and other low molecular weight components, will migrate through the filter to a collection well on the opposite site of the filter. Bound analyte will remain with the plasma proteins on the top half of the device, which is then discarded. The analyte-containing filtrate samples are then quantitatively assayed, in addition to unfiltered plasma spiked with analyte, once the centrifugation cycle is finished. The analyte percentage bound is then calculated using the following formula:

$$\left[\% \text{ Unbound} = \frac{\text{Drug concentration in ultrafiltrate post centrifugation}}{\text{Drug concentration in plasma pre centrifugation}} \times 100 \right]$$

Ultrafiltration is a relatively quick, inexpensive, and simple experiment to conduct but does suffer serious problems and inaccurate values due to compound adsorption to the top half of the filtration device. This can lead to serious overestimation of protein binding.

23.3.2 Equilibrium Dialysis

Equilibrium dialysis is generally regarded as the gold standard method for obtaining plasma-protein-binding information [11–16]. In addition to improvements in

TABLE 23.1 Comparison of *In Vitro* Methods of Plasma Protein Binding

Techniques	Advantages	Issues
<i>Traditional Techniques</i>		
96-Well ultrafiltration	% Binding Commercially available plates Automated	Nonspecific binding Must correct for volume shifts Not true equilibrium experiment
96-Well equilibrium dialysis	% Binding Automated “Gold standard” Flexible	May require long equilibration times Long-term plasma stability of analyte at 37°C may be problematic Devices not widely available
96-Well ultracentrifugation	% Binding Automated	Requires ultracentrifuge or long centrifugation times May generate errors because of lipoprotein interactions in supernatant
<i>Screening Techniques</i>		
Chromatographic methods (Human Serum Albumin, α -AGP columns)	Easy setup Low cost Relative low sample consumption Minimal hands-on preparation or intervention	Binning/relative ranking not absolute percentage binding
96-Well Fluorescence	Rapid Automated Easy setup K_d	Monitoring binding only to tryptophan residue of Human Serum Albumin and α -AGP May miss other binding interactions
Biosensor (Biacore)	Semiautomated % Binding and K_d	Higher time commitment and cost for setup More sample may be required Skilled operator required Solubility issues may be encountered
TRANSIL™ Membrane	Rapid Automated Sensitive % Binding and K_d	Individual proteins or blend of key proteins Not physiological conditions
Capillary electrophoresis	% Binding and K_d Wide dynamic range of K_d Online determination—no sample preparation required	Poor sensitivity Poor reproducibility Compound adsorption to capillary walls Highly acidic compounds problematic
Solid-phase microextraction	% Binding No sample preparation 96-well format	Not commercialized May observe sensitivity limitations and binding saturation for highly bound compounds

throughput via 96-well formats (see below), recent work at Astra Zeneca has shown that compound pooling may be utilized to increase the number of compounds assayed in a single experiment to as many as 10 [15]. On the basis of the high protein content in plasma (30–50 mg/mL HSA, 0.75 mg/mL α -AGP) relative to analyte concentration (typically 10–1000 ng/mL), compound pooling offers a simple but powerful mechanism to quickly obtain screening information. However, if multiple compounds bind specifically to α -AGP, pooling may introduce erroneous results compared to single-compound incubations.

Three different 48- or 96-well commercial equilibrium dialysis devices have been introduced since 2005. In the HT-Dialysis apparatus, eight dialysis membranes are vertically mounted between Teflon spacers that comprise the individual wells [14]. Owing to the vertical design, 96-well liquid handling devices can be used for automated buffer and plasma transfers. The device itself is reusable, with the membrane serving as the primary device consumable. The 96-well Dispo-Equilibrium Dialyzer proposed by Kariv *et al.* [17] utilize a single horizontally mounted dialysis membrane contained in a single-use unit. Use of liquid handling automation for sample handling is still feasible with the horizontal design, albeit with user intervention. The 48-sample Pierce Rapid Equilibrium Dialyzer (RED) system [16] offers a faster equilibrium time (1–2 h) because of a large surface area/volume ratio.

In a typical equilibrium dialysis experiment, blank phosphate buffer solution is added to one side of the dialysis membrane in each well and an equal volume of analyte-spiked plasma to the other side. The equilibrium dialysis device should be incubated at 37°C in a CO₂ atmosphere or with a strong phosphate buffer [17–19] to minimize plasma pH shifts over the experimental time course. Work done by Kochansky *et al.* has shown that pH may increase to 8.7 over 22 h incubation under ambient conditions [18]. This pH shift may alter the protonation state of the analyte thus affecting plasma protein affinity. Once the incubation is complete, individual aliquots are taken from both the plasma and buffer sides and quantitatively assayed by either LC-MS/MS or radiometry.

The analyte free fraction (f_u) is calculated using the following equation. This equation assumes that error added because of a Donnan equilibrium volume shift [20,21] is within the error of the assay method, and therefore negligible. The volume shift may be observed with long equilibrium times such as 24 h; however, compounds or devices that allow a rapid equilibration time of 4 h are unlikely to result in a significant shift.

$$f_u = \frac{C_{\text{buffer}}}{C_{\text{plasma}}}$$

where C_{buffer} is the unbound compound concentration in buffer after dialysis and C_{plasma} is the postdialysis plasma concentration.

The percent of drug unbound (free) and bound to protein are calculated as follows:

$$\% \text{ Free} = f_u \times 100$$

$$\% \text{ Bound} = (1 - f_u) \times 100$$

A potential problem and source of high variability with equilibrium dialysis is protein breakthrough from the protein-rich plasma side to the aqueous side of the dialysis cell, causing false elevation in the buffer compound concentrations. This can be

monitored by taking an aliquot of any remaining buffer, adding acetonitrile to precipitate the protein, and checking the solution for visible particulates. Use of a membrane with appropriate molecular weight cutoff (10 kDa minimum) will help prevent this problem.

During equilibrium dialysis, an equilibration time of 24 h is recommended for the sake of efficiency. However, scientific judgment can be utilized to reduce this time to 4, 6, or 8 h. Equilibrium dialysis devices that allow for agitation may allow for a faster achievement of equilibrium. For definitive data, it is important to assess at least two sequential time points to ensure that equilibrium has been reached. Analytes can be lost during equilibrium dialysis by nonspecific binding to the membrane and apparatus, decomposition of the compound, or solubility issues. Assessment of this loss can be performed in a separate recovery experiment or during determination of equilibration time. As equilibrium dialysis is a comparative technique, the two halves of an individual well should exhibit similar non-specific binding or recovery issues, thereby minimizing negative impact.

23.3.3 Ultracentrifugation

Ultracentrifugation of plasma results in a protein pellet and an essentially protein-free supernatant [22–25]. Plasma is spiked with the test compound. After centrifugation at 200,000 relative centrifugal force (RCF) for 18 h or 550,000 RCF for 4 h at 37°C, the protein bound material is pelleted with the proteins. The unbound drug material remains in the supernatant, which can be analyzed by radiometric or LC-MS techniques depending on whether the test article is radiolabeled. Generally, it is advisable to take a fraction of the supernatant from the center of the tube to avoid lipids, which may lie at the surface, and any drug concentration gradients that may occur as a result of the centrifugation. This technique largely avoids the problem of nonspecific binding to the apparatus; however, it is a low throughput method requiring an ultracentrifuge. For compounds with high plasma protein binding observed with equilibrium dialysis or ultrafiltration, it can afford a suitable alternative because it may reduce the impact of confounding factors such as solubility and nonspecific binding. The main disadvantage of ultracentrifugation relates to the presence of trace amounts of lipoproteins in the “protein-free” supernatant and highly bound drugs may be associated with these macromolecules. Therefore, compounds measured as free drug in the supernatant may actually be bound, and this will lead to an artificially high free fraction determination.

Buffer controls are used to test for nonspecific binding to the tubes. One option is to test at a concentration that is equivalent to 1% (assuming a 99% protein bound compound) of the lowest concentration tested to mimic the free fraction of a highly bound compound.

The equation used for calculations is as follows:

$$\% f_{\text{up}} = \frac{\text{Measured drug concentration post ultracentrifugation}}{\text{Measured drug concentration pre ultracentrifugation}} \times 100$$

23.3.4 Detection—Radiometric or LC/MS/MS

Radiometric detection had been the classic method of quantitation for plasma protein binding until the invention and broad use of LC/MS/MS methodology. The use of

tritium or carbon-14 labeled materials allow a facile determination of absolute recovery from the various plasma-protein-binding devices and a ready measure of drug amount. A potential drawback of radiometric determination occurs for very highly bound drugs and relates to the purity of the label. When the percentage of radiochemical purity of the radiolabel approximates the percentage of plasma protein binding, it is possible that the unbound material measured is actually impure rather than drug material. This puts the results into question. For this reason, the use of LC/MS/MS may afford a more accurate measure for very highly bound drug candidates. The use of standard curves to ensure quantitative measure and comparison to appropriately spiked control samples will allow quantitation for the purpose of recovery calculations.

Historically, highly bound compounds were considered to be those with binding of >95%. With current techniques (either highly pure radiolabel or the use of LC/MS/MS), accuracy within this range has improved considerably and the current limit is considered to be ~99%. If one considers a 10 μ M concentration, 1% unbound material that represents 100 nM, a reasonable limit of detection for LC/MS/MS methods.

23.4 EMERGING TECHNIQUES

Exploratory work continues to investigate new opportunities to improve plasma protein binding beyond the previously described high throughput traditional approaches. These so-called “Emerging Techniques” employ methodologies ranging from chromatography, CE, spectroscopy, biosensors, microextraction, and model artificial membranes. Table 23.1 describes the relative advantages and issues for traditional and screening *in vitro* plasma-protein-binding techniques.

23.4.1 Chromatographic Methods

Significant effort has been invested over the years in assessing plasma protein binding through chromatographic methods based on HPLC columns containing the most abundant plasma proteins, HSA and α -AGP [26–33].

Through the usual chromatographic partitioning processes, binding can be correlated with chromatographic retention time. In a typical experiment, the capacity factor (k') of each compound is calculated based on its retention time, using the following formula:

$$k' = \frac{t_r - t_m}{t_m}$$

where t_r is the retention time of the analyte and t_m is the retention time of an unretained compound, also known as the *column void volume*, and t_m can be assessed using glucose, cesium iodide, or ammonium nitrate. From the k' values, $(k'/k' + 1)$ is calculated and then plotted as a function of the known plasma protein binding, as shown in Fig. 23.3. After the correlation plot is generated, the plasma protein binding of unknown compounds can be calculated based on their retention time on the albumin or α -AGP column. In general, the factor $k'/k' + 1$, rather than k' , shows better linear correlation with plasma-protein-binding values. As shown in the Fig. 23.3, compounds can be binned into low, medium, and high protein-binding categories, to aid in screening. When first establishing the method in one's laboratory, a series of compounds with

Figure 23.3 Binning of low, medium, and high plasma protein binding by chromatographic retention.

known plasma-protein-binding values should be chromatographically analyzed using an HSA column. In addition, an α -AGP column may be used in series or parallel. The degree of plasma protein binding can be either found in the literature [34,35] or obtained by comparative ultrafiltration or equilibrium dialysis.

Recently, both Hage and coworkers and Wainer and coworkers have published reports on the use of in-house prepared HSA affinity microcolumns for plasma-protein-binding determinations [36–38]. Both frontal affinity and zonal elution chromatography have been utilized, each with its own advantages and disadvantages. The primary stumbling block to widespread application of these techniques within the pharmaceutical industry is the commercial availability of the HSA microcolumns.

In practice, most pharmaceutical laboratories screen only against the HSA column, accepting the risk that binding α -AGP or other less-abundant serum proteins may be completely underestimated. This method generally performs better for compounds exhibiting low to moderate plasma protein binding rather than high (>95%).

23.4.2 Capillary Electrophoresis Methods

The application of CE to the measurement of plasma protein binding represents a logical mechanism to leverage the inherent ability of CE to separate analytes based on electrophoretic mobility. CE techniques utilized for this purpose essentially examine the difference in analyte mobility in bound and unbound states to various proteins. Affinity capillary electrophoresis (ACE) techniques have been utilized for relative rank ordering of compound libraries versus various protein receptors [39], which can be measured during the separation step or against a solid-phase ligand support. This methodology offers the advantages of small sample volume requirements, relatively rapid measurements under equilibrium conditions, and at pH 7.4 “near physiological conditions,” similar to traditional techniques such as equilibrium dialysis. In a study conducted by Ishihama *et al.* [40], this technique was applied to six anionic drugs. Their binding to HSA correlated with values obtained by ultrafiltration over a range of 78.7–99.9% binding, with typical reproducibility <10% CV (coefficient of variation). However, the required drug concentration in solution was 20 μ M.

Figure 23.4 Illustration of single-run measurement of protein binding by high performance frontal analysis capillary electrophoresis. H1 and HB are the peak plateau heights of the drug standard and the drug resolved from the drug–protein mixture, respectively. $\%F_u$ is the unbound free fraction of drug to specific protein.

Higher sample volume online approaches can be leveraged by combining frontal analysis with CE. Figure 23.4 shows a schematic of this process, described as frontal analysis capillary electrophoresis (FACE). An injection of neat analyte solution is made, followed by a buffer plug, and subsequently by an injection of analyte + protein mixture. On the basis of binding equilibria as well as relative electrophoretic mobility, the resulting electrophoretogram will contain a free analyte peak, which can be used as a relative standard response against a separate, later eluting peak corresponding to analyte not bound to the protein of interest. Depending on experimental conditions, the unbound analyte peak may or may not be resolved from the protein peak and may instead appear as a shoulder on the larger protein peak. CE is most commonly coupled with UV detection and was leveraged for plasma-protein-binding experiments in a study of protein–drug binding constants for HSA and α -AGP [41,42]. More recently, commercial interfaces to mass spectrometers have been developed and utilized for plasma-protein-binding determinations [43]. The analyte concentrations required can be decreased from the ≥ 1 mM to <20 μ M range. Better correlation of percentage binding values were observed with the plasma was diluted to 10% plasma in buffer. In addition, a dependence of percentage binding on time interval between sample injections was observed. It was hypothesized that because of significant lower concentrations for MS detection compared to UV resulted in differential adsorption of the analyte to the capillary walls, rather than saturation at high concentration. This technique provides rapid screening values but has not yet matured to a stage where precise percentage binding values can reliably be obtained, particularly for highly bound compounds.

23.4.3 Spectroscopic Methods

The 96-well fluorescence approach relies on the detection of intrinsic fluorescence of the tryptophan residues of HSA and α -AGP, the primary plasma protein constituents [44]. As drugs bind to the protein, the fluorescence signal is quenched as a function of analyte concentration. The analyte's dissociation constant, k_D , can then be calculated. Although this method is readily automated, its universality is questionable, since tryptophan residues reflect only a portion of the potential binding sites to both α -AGP and HSA.

23.4.4 Biosensors—Surface Plasmon Resonance

Another high throughput technique for plasma protein binding utilizes the Biacore™ surface plasmon resonance (SPR) technology as shown in Fig. 23.5 [45–48]. Proteins of interest are immobilized onto a gold foil. The drug is exposed to the proteins, binding occurs in real time, causing a change in refractive index of a light beam. The kinetics of both the on-rate and off-rate is captured in a sensorgram. After determining the dissociation k_D values from sensorgrams of multiple solutions containing several concentrations of drug, the corresponding percentage binding can be calculated. The binding to both albumin and α -AGP is combined to give the overall plasma protein binding for these two proteins. If binding to proteins other than albumin or α -AGP are important, the plasma protein binding will be underestimated. The need to purchase Biacore SPR instrumentation as well as instrument and chip synthesis proficiency can be potential limitations.

SPR has the potential to become a very high throughput technique since the use of microfluidics and the generation of protein arrays on the chip allow for highly multiplexed approaches [49]. Although this technique requires a significant amount of time and expertise to establish, once operational, it can provide extremely high throughput results. In addition, the potential to address the critical gap of very high bound plasma-protein-binding determination is an intriguing future prospect.

Figure 23.5 Experimental approach and equipment required for Biacore™ analysis of binding by surface plasmon resonance.

23.4.5 Solid-Phase Microextraction

Solid-phase microextraction (SPME), pioneered by Janusz Pawliszyn and coworkers [50], represents one of the more recent developments in general analytical sample preparation. This methodology relies on the extraction of the analyte of interest from liquid or gaseous media onto a solid support, generally a polymeric coating on a metal rod. The microextraction probe is engineered in a manner to enable maximal surface contact and ultimately analyte adsorption. This technique has been utilized to determine plasma protein binding for a set of pharmaceutical compounds including ibuprofen, warfarin, verapamil, propranolol, and caffeine with low, intermediate, and high protein-binding properties. Good correlation was observed between literature and SPME-derived protein-binding values. Figure 23.6 shows a schematic of the SPME experimental design for protein binding. Several variables were optimized including choice of fiber material, pH control mechanisms, and plasma dilution with phosphate buffer saline (PBS). Plasma dilution serves a very useful purpose of allowing highly bound ($>99.9\%$) drugs to be reliably quantitated by decreasing the amount of plasma proteins and correspondingly, the percentage bound. Although commercial devices for this technique are not yet available, exciting possibilities for 96-well parallel extraction designs can be easily envisioned.

23.4.6 TRANSIL™ Membrane and Protein Beads

The TRANSIL™ membrane beads are used to replace erythrocytes [51] in partitioning assays and are uniquely suited to plasma-binding determinations for highly bound or low aqueous solubility drugs [52,53]. In this assay, the analyte is incubated together with plasma and the membrane beads for 30 min. By determining drug concentrations in plasma after incubation, the assay circumvents issues with compounds with poor aqueous solubility. This assay monitors the decrease in analyte plasma concentration rather than the appearance of analyte in another phase (buffer). As essentially an indirect measurement, the need for ultrasensitive quantitation for highly bound drugs is avoided.

To determine the affinity of drugs to plasma, the change in affinity to the membrane beads, induced by changing the plasma concentration, is measured. The fraction

Figure 23.6 Schematic representation of experimental setup for the determination of plasma protein binding by solid-phase microextraction (SPME).

Figure 23.7 Illustration of TRANSIL™ beads and approach for measuring binding using beads embedded with plasma proteins.

bound is calculated from linear regression of membrane affinity (M_A , Y) measurement data obtained from different plasma dilutions (D_{plasma} , X). The calculated slope α and intercept M_{A0} are then inserted into the following equation:

$$f_b = 1 - \frac{1}{1 + \alpha M_{A0}}$$

This approach allows accurate measurement of free fractions of 0.01 or lower.

A rapid technique for predicting plasma binding from affinities (K_d) to HSA and AGP is provided by the TRANSIL protein bead assay system based on HSA and α -AGP mobilized on silica beads. The beads are suspended in a solution of drug and after a few minutes, centrifugation is performed to separate the beads as shown in Fig. 23.7. Versions of the assay exist for HSA, AGP, rat albumin, and HSA and AGP mixed together at a ratio of 24:1 to mimic plasma conditions. Quantitation of analyte remaining in the supernatant may be quickly and reproducibly measured by radiometry or LC/MS/MS, as appropriate

23.5 IMPACT OF HIGH (UNDETERMINABLE) PROTEIN BINDING ON COMPOUND DEVELOPABILITY

It is common that highly lipophilic drugs may exhibit very high plasma protein binding, in excess of 99%. Owing to analytical limitations, the accuracy of determinations above 99% bound are not reliable when radiometry or LC/MS/MS is involved. For radiometric determination, the radiolabel must be >99% pure in order to be confident that the free fraction observed is because of drug and not impurity. Radiolabel with this degree of purity may be very difficult to obtain and is well above the purity typically required for other purposes such as excretion or metabolite profile studies

where 95% radiochemical purity is sufficient. For LC/MS/MS, a 99% plasma protein bound (PPB) compound would yield 1% free, leading to 10 nM LOQ for a study conducted at a typical 1 μ M starting concentration. This LOQ is readily measurable for most NCEs (new chemical entities) but not necessarily with the requisite precision and accuracy to report greater than unit percentage binding values with confidence. Most LC/MS/MS methods rely on relatively simple generic sample extraction methods (protein precipitation) as well as chromatographic and mass spectrometric conditions. The emphasis of method development at the time protein-binding assays are conducted is generally on speed (turnaround time), not exquisite sensitivity. The most pragmatic approach taken, if LC/MS/MS sensitivity cannot be readily improved, is to simply report >99% binding and move on to the next experiment.

The inability to accurately determine the plasma protein binding is an issue because it is the free fraction that is important for the determination of PK/PD and safety margins. Above 99% binding, the corresponding free fraction is 1% or less and differences become pronounced. For example, the difference in free fraction between 99.4% and 99.8% is a factor of 3; 0.6% versus 0.2% free. Analytical methods that provide inadequate sensitivity and corresponding LOQ seriously hamper decision making. Inability to precisely and accurately determine percentage binding values for very highly bound compounds seriously limits accurate PK/PD interpretation from preclinical species or prediction of necessary dosing regimens that will provide efficacious doses in the clinic.

In situations where the PPB is very high, one recommended approach is to conduct the experiment with plasma that is diluted to 10% in phosphate buffer solution. The undiluted plasma result can then be back calculated to plasma binding by the equation [54], where D and $F_{u, \text{measured}}$ represent the fold dilution of plasma and unbound fraction measured with diluted plasma, respectively.

$$\text{Undiluted } f_{\text{up}} = \frac{1/D}{\left[(1/F_{u, \text{measured}}) - 1\right] + 1/D}$$

23.6 CONCLUSIONS

Plasma protein binding is clearly an important ADME parameter required to understand drug efficacy and possibly toxicity. Recent progress in automation as well as increased routine performance of the analytical instrumentation has enabled a greater number of compounds to be assayed earlier in discovery, often at a high enough quality level such that repeated determinations later in development are not needed. Significant challenges still remain unsolved, particularly in cases of high protein binding with low exposure levels that fall below the normal LOQ. As technology improves even further, we can expect more opportunities to understand and leverage this important information to an even greater extent.

1.1 INTRODUCTION

1.1.1 Clinical Drug Usage

Over the past 30 years, enormous strides have been made in drug development. The combination of the pharmaceutical industry and government regulatory agencies has to a remarkable extent, produced entirely new drug classes which can not only cure or control many serious and debilitating diseases but also achieve this in many cases with minimal toxicity. Cardiovascular and malignant disease, for example, the largest killers in the developed world, have been treated with a variety of new and demonstrably effective drug regimens, such as the statins, angiotensin converting enzyme (ACE) inhibitors, as well as the taxanes, camptothecins, and tyrosine kinase inhibitors. These drugs have alleviated mortality and morbidity and several previously untreatable and invariably fatal conditions such as AIDS have been clinically redefined since the 1980s through combination drug therapy as serious, but now nonfatal and chronic, yet manageable diseases.

Indeed, the relatively narrow choice of toxic drugs available for other debilitating neurological conditions such as schizophrenia, depression, bipolar disease, and

epilepsy up to the end of the 1970s has also been vastly widened with the selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) as well as several new neurileptics and antiepileptic drugs (AEDs), which are, in most cases, significantly less dangerous for vulnerable patients, in terms of safety in overdose as well as reduced toxicity. Such advantages also have the added benefit of promoting compliance.

Naturally, none of these advances have been risk free and there are many reasons why drugs may cause adverse effects of various kinds. Some of these problems are very difficult to predict as they are the result of complex pharmacological, physiological, biochemical, and genetic interactions. Such effects may only emerge after many years and sometimes decades of use. The association of long-term β -blocker usage and their promotion of the risk of diabetes [1] was one such problem, and it is likely that the existing risks of several drugs used in mass therapy such as the statins [2] may be compounded by others that may perhaps only emerge in subsequent decades. Sometimes, these risks are balanced by benefit in control of symptoms and increased longevity [3] and as well as other positive off-target effects, such as the possible beneficial effects of statins on dementia [4].

More immediately, there are many factors that can govern day-to-day drug efficacy and adverse reactions that are also difficult to predict. These include receptor numbers and activity (e.g., downregulation), pharmacological interactions, protein and deep tissue binding, as well as abrupt changes in renal clearance. However, the single greatest influencing factor on whether a drug exerts a therapeutic or a toxic effect is its concentration at the receptor sites in the target organ or organs. Of course, receptor concentrations are not necessarily the same as what is broadly termed systemic drug concentrations and any relationship between the two is strongly linked with the physicochemical characteristics of the drug and their influence on its tissue distribution. Nevertheless, systemic concentrations are usually all that can be measured in clinical practice and these concentrations can usually be linked with pharmacological action. This relationship tends to hold for drugs such as AEDs but not for drugs monitored pharmacodynamically, such as warfarin. Assuming dosage is regular and absorption is reasonably complete, systemic drug levels and indeed, drug bioavailability, are themselves dependent on the various processes of biotransformation that occur in the liver, gut, lung, and kidney, which clear the drug either “pharmacologically,” by causing structural changes which reduce or eliminate therapeutic action, or through complete removal from the body in the process of excretion.

1.1.2 Biotransformation and Drug Efficacy and Toxicity

It cannot be overemphasized that biotransformation as a process is a network of coordinated systems that possesses two governing objectives: essentially to “serve and protect.” In terms of “service,” biotransforming enzymes are responsible for the myriad reactions behind the assembly of millions of bioactive endogenous chemicals that, like hormones and other influential small molecules, are responsible for second-by-second homeostatic tasks, through to long-term and permanent comprehensive bodily changes such as those associated with puberty and the maintenance of reproductive capacity. “Protection” involves the control of the cellular environment to ensure that endogenous molecules are confined to half-lives that are commensurate with their purpose, as well as the rapid elimination of interloper molecules such as the classic exogenous

endocrine disruptors, which are now ubiquitous in our environment. As far as biotransformational systems are concerned, drugs fall into the “protect” category and as with any system that has evolved to serve and protect, it must be aware of its environment. Hence, biotransformation is sensitive to challenge by exogenous as well as endogenous chemical entities. Drugs such as many AEDs and some antibiotics such as rifampicin exert powerful enzyme-inducing effects on biotransformation, aimed at expediting their clearance, while inhibitors such as grapefruit juice and azoles shut down crucial aspects of biotransformational capacity to the potential detriment of the individual. Into this dynamic, sensitive and highly efficient system, drug therapy is pitched and considering the high state of evolution of biotransformation, it is remarkable that drug treatment outcomes are as good as they are.

Biotransformation's impact on drug efficacy and toxicity is transmitted through changes in clearance. If an inducer drug is added to a regime, biotransformation of the enzymes that process that agent and indeed many others will increase by several fold to a point of maximal stability, provided the inducer dosage is maintained. The resultant acceleration of the clearance of this drug and many others will cause their respective levels to fall out of the therapeutic window and drug efficacy will diminish and eventually be lost. In contrast, if a potent inhibitor of biotransforming enzymes is added to a regime, then clearance will slow and possibly stop, leading to drug accumulation if the dosage is maintained. This can lead to intensification of the normal profile of pharmacological effects, as well as off-target effects, which are unconnected to the original purpose of the drug, but nonetheless exert considerable impact on the patient. These changes are to some extent predictable and are dose related. Biotransformation can be involved in idiosyncratic drug toxicity through the consequences of the formation of reactive species during metabolic processes. Although biotransformation is not the only mechanism at work in idiosyncratic drug reactions, these effects are notable by their unpredictability and lack of relation to dosage or duration of therapy.

1.1.3 “Real-World” Drug Usage

It could be considered that the patient is vulnerable to problems with drug concentration at two key stages in their therapy. The first is the initial consultation with a healthcare practitioner when drug therapy is prescribed. The second stage might be considered when changes are made in an established drug regime. These two critical stages are themselves influenced by what could be termed underlying factors, such as patient age, gender, pharmacogenetics, diet, and pharmacologically active substance intake, licit, and illicit. What could be termed dynamic factors such as the use of a drug which is either an inhibitor or inducer of biotransformation also applies to these stages.

The potential for these underlying and dynamic factors to influence drug treatment outcomes is very considerable. For example, when a drug regime is initiated, a standard recommended dose may be suitable for the majority of patients, but may lead to accumulation in the elderly and neonates, who possess reduced biotransformation capacity [5]. The prescription of an inhibitor of biotransformation may cause a similar drug accumulation problem. Alternatively, gender can influence rates of biotransformation as females clear many drugs more rapidly than males [6]. These effects, as well as inducing drugs, may seriously jeopardize drug therapeutic success by accelerating clearance from the body.

Of the remaining major influences on biotransformation and prescribed drug outcomes, two are particularly problematic and often interrelated; these include

polypharmacy [7] and the emerging phenomenon of patient self-medication [8]. Of course, these factors may combine, where patients on complex drug regimes may cause serious disruption to their drugs' efficacy and toxicity if they self-medicate with herbal preparations such as St. John's Wort. However, what is of concern is that there are some parallels between the two situations in terms of impact on some selected and vulnerable patient groups. Complex drug regimes are most common in the elderly and those who are under specialized treatment, such as those who have received xenografts, or those under cancer chemotherapy. All these conditions (if being elderly can be described thus) have a powerful impact on patient health, well-being, and particularly mental state. Patients are internally motivated to self-medicate to "assist" therapy, perhaps through taking antioxidant supplements or dietary products during cancer treatment. Conversely, the stress and uncertainty of major therapy may promote the use of herbal antidepressants in cancer chemotherapy and organ graft. Hence, a complex pathology may result, involving factors such as age, gender, and impact of disease that are compounded by polypharmacy. Drug clearance is likely to be strongly affected, leading to problems with toxicity, drug efficacy, treatment outcome, and even life expectancy. Perhaps most worryingly, many patient-motivated changes to diet and medication may occur without the consent or knowledge of the healthcare professionals responsible for the patient's optimum care.

While there are many issues discussed earlier in terms of the management of patient care, what is of paramount importance is the realization and some understanding of the pivotal role of drug biotransformation in patient healthcare outcome. The following chapter will outline some of the major features of the hugely dynamic and almost infinitely adaptable human biotransformation process.

1.2 BIOTRANSFORMATION: MAJOR COMPONENTS

1.2.1 Transporters: Influx

A powerful influence on drug efficacy and toxicity is the process of "first pass," which dictates bioavailability. While for many years the major biotransforming enzymes such as the cytochrome P450s (CYPs) and the glucuronosyl transferases were seen as the major influence on bioavailability, it is now apparent that many more biotransformationally coordinated systems, such as transporters, make a substantial contribution to first pass. The complexity of these systems is rooted in the somewhat contradictory roles that the gastrointestinal (GI) tract is required to play, concerning the simultaneous selective uptake of key nutrients that would not be otherwise absorbed and the role of "gatekeeper" [9], which is necessary to repel potential toxins. Indeed, it cannot be assumed that the most basic step toward a therapeutic effect, that is, drug absorption, is always a simple matter of passive diffusion. While many agents are passively absorbed through membranes due to their lipophilicity, there are others whose physicochemical properties preclude this step, such as amphipathic chemicals. These contain polar as well as nonpolar regions and as such can be excluded from passive membrane diffusion. Hence, amphipathic drugs must avail themselves of transport systems that normally import nutrient amphipathics such as amino acids and bile salts. The organic anion-transporting polypeptides (OATPs) usually exchange such molecules in return for the export of a thiol such as glutathione (GSH). Several amphipathic drugs depend

on the OATPs to be translocated across not only the gut but also the liver. Interestingly, depending on the specific site of the OATPs, diametrically opposed effects on drug bioavailability can result. In the gut, inhibition of OATPs by agents in fruit juices can dramatically reduce the uptake of the antihistamine fexofenadine [10], and these juices can also affect thyroid hormone supplementation [11]. In contrast, further along the process of presystemic absorption, several drugs such as the statins pravastatin and rosuvastatin appear to depend on organic anion-transporting polypeptide 1B1 (OATP1B1) for hepatic uptake from the portal blood supply. One of the best clinical examples of drug–drug interactions (DDIs) concerning the OATPs is the effect of cyclosporine on statin bioavailability. Patients who have received xenografts such as whole organs often have lipid metabolism that is abnormal enough to warrant statin treatment. However, when their main immunosuppressing therapy includes cyclosporine, this drug is a potent inhibitor of hepatic OATP1B1, so the normally extensively metabolized statins evade hepatic uptake and up to 20-fold systemic increases in statin plasma concentrations can result; this can lead to severe muscle toxicity (rhabdomyolysis) [12,13]. Interestingly, not all immunosuppressant drugs cause this effect, as tacrolimus, for example, does not appear to interfere with OATP1B1 [14]. Both influx and efflux transporters (described below) are indirectly sensitive to substrate pressure and are regulated through the same system that controls CYPs and glucuronyl transferases (UGTs) (Section 1.3.1 and 1.3.5).

1.2.2 Transporters: Efflux

The most extensively investigated transporter that is chiefly concerned with expelling drug-like molecules is P-glycoprotein (P-gp, also known as ABCB1). This protein is one of several adenosine-triphosphate (ATP)-binding cassette efflux transmembrane transporters, known as the ABC transporters. They are part of a raft of protective efflux systems that exert a powerful influence on cellular environments. These include the various multidrug resistance-associated proteins (MRPs) and breast cancer resistance protein (BCRP or ABCG2). P-glycoprotein (P-gp) is intensively studied, as it is ubiquitous in tissues and aside from its gastro-intestinal tract (GIT) protective function, it is one of the first lines of defense against antiproliferative agents in malignant cells and has been implicated in resistance to antiepilepsy therapy. P-gp is often described as promiscuous in its binding of substrates, although there seems to be almost as many apparent inhibitors as substrates of this transporter, so the overall picture as to how different substrates and inhibitors influence each other's penetration into tissues is extremely complex and is not readily predictable. This is partly due to the vast numbers of dietary chemicals that may also interact with P-gp. It is apparent that some deleterious drug interactions are rooted in the role of P-gp. The intensification of cyclosporine-mediated renal toxicity in the presence of coadministered sirolimus is linked with the latter agent's inhibition of P-gp [15]. Some efforts have been made to manipulate P-gp through the use of inhibitors such as verapamil, which in studies with human hepatocytes, can increase drug residence time and promote oxidative metabolism of raloxifene [16]. P-gp is controlled through the pregnane-X-receptor (PXR) induction system (Section 1.3.2.1) and is responsive to drug pressure. It is likely that the major research effort to modulate P-gp clinically will be most effective in the area of cancer chemotherapy resistance attenuation, rather than in drug GIT absorption and metabolism.

1.2.3 Cytochromes P450

1.2.3.1 Introduction. Once a therapeutic agent has either been passively absorbed, perhaps transported by OATPs or P-gp, its next obstacle to surmount before reaching the systemic circulation is probably the ultimate cellular biotransformational force, the CYPs. These enzymes are found in virtually every tissue, but the endoplasmic reticulum of gut and liver cells are particularly rich in cytochromes P450 or CYPs as they are usually termed. These lipophilic enzymes are responsible for more than 70% of drug clearance and possess several unique features that effectively ensure that most present and future pharmaceutical agents can be biotransformed to some degree. CYPs are thought to have originated in bacteria in the early stages of life on Earth and their ability to reduce substrates probably reflects the realities of early life in oxygen-free environments. After life became established and larger species colonized the land, one of the most potent drivers of CYP evolution within animal life is thought to have been the development of the defensive capability necessary to survive various plant toxins as animals established their habitats [17]. Interestingly, present-day bacterial CYPs such as CYPBM3 (102A1) are capable of metabolizing several therapeutic drugs, such as nifedipine and propranolol [18] and only modest bioengineering is required to widen the catalytic capabilities of such bacterial CYPs enormously [19].

CYP evolution has allowed the vast range of eukaryotic life to effectively manage the problems of the manufacture of required endogenous molecules such as hormones, their control, and destruction, alongside the threat from potential xenobiotic endocrine disruptors. To succeed in all these areas over billions of years would almost certainly not be possible using a somewhat restrictive basic “lock-and-key” enzymatic approach. While these enzymes really only act as monooxygenases and place a single oxygen atom into a substrate, the key to CYP success is their ability to apply this single process to a vast array of chemical structures that in turn, leads to a variety of fundamental rearrangements in the structure of the substrate that then causes significant physicochemical changes. These two latter features govern the main pharmacodynamic and pharmacokinetic behaviour associated with a particular drug, toxin, or hormone, usually expediting clearance and subsequent loss of therapeutic impact.

CYPs achieve this through their ability to retain the relative rigidity of their active site, while exhibiting extraordinary flexibility in their ability to bind substrates. Although other biotransforming systems can achieve this, an inkling of the sheer versatility of CYPs has been gained of their flexibility indirectly through the evaluation of many crystal CYP structures where a variety of substrates are bound in unique structural conformations. Hence, CYPs apply the “induced fit” rather than “lock-and-key” model of substrate binding [20], rather like a human hand grasping an object that is aligned toward the palm as the active site [21].

The CYPs are generally identified through their respective gene families (e.g., CYP1 and CYP2) and at least 40% sequence homology aligns a particular CYP to others within that family, while the subfamilies (e.g., CYP1A and CYP2A) are classified according to at least 55% homology. Particular CYP isoforms controlled by a single gene are classified through a number following the subfamily letter, such as CYP1A1 and CYP1A2. Although there are 18 human gene families and 44 subfamilies, many CYPs are engaged with functions other than the metabolism of xenobiotics, such as the complex machinery for the synthesis of the various hormone molecules. Others are

engaged in modulation of brain chemistry and circulatory control. The major families that are of relevance to xenobiotic (i.e., drug and potential toxin) clearance include the CYP1, 2, and 3 families [17].

1.2.3.2 CYP Biotransformational Impact. Alongside most human enzyme systems, the CYP families are mostly highly polymorphic [17], where several alleles exist of the same gene with massively varying degrees of expression and catalytic capability. Indeed, in many cases, particular alleles are absent from considerable proportions of some human populations. Whilst over the millennia, the forces that have shaped differential human expression of CYPs include exposure to various chemical agents in diet and the environment, the net effect is to safeguard the whole population from a single toxin, at the expense of individuals. This enormous strength of our species unfortunately translates into a major problem for drug development, where one size definitely does not fit all.

As CYPs are effectively the major force in drug biotransformation and they affect clearance, drug residence time and efficacy to a critical degree, any changes in their metabolic processes will have profound effects on drug therapeutics. If they are simply not expressed as described above, or inhibited by other coadministered drugs, then their failure to clear their respective substrates will result in drug accumulation. This is initially often translated into “off-target” therapeutic effects that are unintended and often problematic, leading to frank toxicity and even death in the case of torsades des pointes (TdP; Section 1.5.4.2). In contrast, if CYP clearance is accelerated for any reason, drug residence time will fall to the point that therapeutic failure may result. Hence, anything that affects CYP performance will crucially affect therapeutic performance, with potentially serious consequences to the patient.

In terms of the impact of CYPs on drug clearance, it is now an oft-quoted statistic that more than half of all prescription drugs are cleared by one CYP isoform, CYP3A4 [22], which comprises around a third of human CYP content [23]. This CYP is found in large quantities in the gut as well as the liver and is probably the most versatile CYP in terms of substrate range, as it can process very large molecules such as cyclosporine, right down to various steroids. CYP3A4 is complemented by CYP3A5, which is expressed in some ethnic groups, but has a very similar catalytic and expression profile to CYP3A4. Although CYP3A4 is not significantly polymorphic in the real world, in therapeutics, it can be problematic as its basal expression varies significantly. It is also vulnerable to a range of inhibitory drugs [24] that are commonly used and often added to regimes where at least one of the drugs used is a CYP3A4 substrate. Consequently, during drug development, enormous efforts are made to investigate the effects of CYP3A4 inhibition in terms of predicting the possible therapeutic impact on coadministered drugs.

Other major CYPs relevant to drug clearance are the CYP2C and CYP2D sub-families, which include CYP2C9, CYP2C8, and CYP2C19 as well as CYP2D6. With the exception of the latter CYP, the CYP2Cs are highly polymorphic and the whole CYP2 family is believed to be responsible for the metabolism of up to a quarter of all prescription drugs [25]. CYP2C9 is of particular interest for its role in the clearance of several agents, particularly warfarin, phenytoin, and a number of nonsteroidal antiinflammatory drugs (NSAIDs) [26], while CYP2C8 also clears some NSAIDs and taxols. CYP2C19 is well documented for its activation of clopidogrel, as well as clearance of proton pump inhibitors such as omeprazole [26]. While the CYP2C variants

are strongly polymorphic, CYP2D6 is particularly interesting as it metabolizes several popular pharmaceutical groups of drugs, ranging from antipsychotics, antiarrhythmics, opiates, and β -blockers and is highly polymorphic but noninducible.

CYPs are generally assumed to be vital in the clearance of prescription drugs, which usually then leads to loss of pharmacodynamic activity. While most metabolites are diminished in therapeutic effect compared with their parent drugs for structural as well as physicochemical reasons, it is important to appreciate the role of CYPs in prodrug therapeutics. Several agents, such as opiates with CYP2D6 (codeine, oxycodone and hydrocodone) and clopidogrel with CYP2C19, depend on CYP metabolism to liberate their therapeutic effects. This introduces some degree of complexity into the study of the effects of CYP variability in activity and expression on therapeutic effect in terms of clearance of parent or prodrug to active constituent as well as clearance from active parent to inactive metabolite.

1.2.4 Glucuronyl Transferases (UGTs)

The uridine diphospho-glucuronosyltransferases (UGTs) are found in close proximity to the CYPs and their primary role is to catalyze the conjugation of various endogenous waste products, such as steroids and bilirubin, with an activated form of glucose (uridine diphosphate glucuronic acid, UDPGA). This has the effect of making the product heavier and much more water soluble [27]. These enzymes are polymorphic and are also capable of directly conjugating several prescription drugs, such as morphine, azidodeoxythymidine (AZT), and lorazepam. Many publications continue to refer to CYPs as “phase 1” and UGTs as part of “phase 2” of drug metabolism. This can suggest that drug metabolism is a sequential, ordered procedure in most cases, which can be misleading. It is true that some agents are firstly oxidized by CYPs and then the product is more likely to be a substrate for the UGTs. However, many agents are directly conjugated by the UGTs without prior oxidative metabolism, so the phase 1/phase 2 nomenclatures can be somewhat restrictive and it has been suggested that it should be abandoned as misleading [28]. The UGTs are certainly capable of clearing a variety of substrates and they are of very high capacity and relatively low affinity, so they are difficult to saturate. There are more than a hundred variants of these enzymes in mammals [29], but in man, only UGT1A, UGT2A, and UGT2B are likely to be relevant to drug clearance.

Until relatively recently, UGTs have been perceived as mainly associated with the clearance of endogenous metabolites and various harmless drug conjugates. However, it is becoming apparent that, in some cases, UGT-mediated drug clearance has a dominant role in drug treatment outcomes that is much more akin to that usually ascribed to the CYPs. This has been notable in the contribution of UGTs to drug adverse effects, which is becoming better documented. For instance, UGT1A3 is particularly efficient at metabolizing steroids such as estrone as well as bile acids. However, the important role of this isoform in the formation of toxic lactone metabolites of statins such as atorvastatin has only recently come to light and their contribution to the myopathy linked with statins remains to be fully investigated [30]. UGT1A3 is also strongly linked with the metabolism of the antiestrogen tamoxifen and the antiepileptic agent lamotrigine.

Interestingly, one of the most marked impacts on drug effect related to UGTs is paradoxically linked with the absence of a UGT due to a polymorphism, rather than their presence. While UGT1A1 is known for its clearance of bilirubin, it also clears the

active metabolite of the antiproliferative topoisomerase I inhibitor irinotecan, SN-38. Accumulation of this metabolite may improve drug therapeutic effect at the expense of toxicity, such as neutropenia. The polymorphic absence of UGT1A1 predisposes a patient to increased risk of irinotecan-mediated toxicity, although this is to some degree preventable through dosage moderation [31]. Other UGTs may also have a role in patients with UGT1A1 deficiencies, such as UGT1A7, whose level of GIT expression is strongly linked with SN-38-mediated gut mucosal toxicity [32].

1.2.5 Sulfonyletransferases (SULTs)

Of the different sulfotransferases (SULTs), some are membrane bound and metabolize proteins and lipids, while the isoforms responsible for drug and drug-like molecule sulfonation are located in the cytosol of most tissues, particularly the gut, liver, and lungs. The SULTs clear a wide variety of endogenous molecules, such as steroids, thyroid hormones, alcohols, and neurotransmitters as well as many widely used drugs such as paracetamol (acetaminophen) and toxic agents such as aromatic amines and polycyclics [33]. They use a cofactor known as 3'-phosphoadenosine-5'-phosphosulfate (PAPS) and it should be emphasized that they "sulfonate" rather than sulfate their substrates, as they introduce a sulfonate (SO_3^-) to various groups, such as hydroxyl or amine moieties. Although sulfonation is usually a detoxification step, resulting in a more water soluble, easily excretable entity (such as paracetamol sulfate), sulfonation is also responsible for the production of many highly toxic species that are DNA reactive. Interestingly, there is some evidence that they also possess sufficient flexibility in their substrate binding to adopt the CYP-like induced-fit method of substrate processing [33].

The SULTs are, as with the CYPs and UGTs, a superfamily of genes and the main families involved in human metabolism include SULT1, SULT2, and SULT4 [34]. SULT1A1 and 1A2 are very structurally similar, while SULT1A3 has <60% homology with the first two isoforms [34]. SULT1A1 is mainly associated with the clearance of iodothyronines and estrogens as well as paracetamol, minoxidil, and various nitrophenol derivatives. SULT1A2 has some overlap in function, although SULT1A3 is mainly responsible for dopamine metabolism [35]. Sulfonation has long been known to be part of the activation of several carcinogenic aromatic amines as well as 2-acetylaminofluorene [36].

1.2.6 Other Biotransformational Pathways

Aside from oxidative metabolism and conjugation, there are several other minor pathways that make contributions to drug clearance, such as amino acid conjugation (hippurate formation) and various hydrolyzing amidases and esterases, which can occasionally make a marked impact on a particular class of drugs. The various plasma esterases clear some neuromuscular blockers such as succinylcholine as well as heroin and cocaine. The monoamine oxidases (MAOs) are found in the liver and gut (MAO-A) and in the brain (MAO-B) and primarily metabolize monoamine neurotransmitters, such as norepinephrine and dopamine, as well as other amines, such as tyramine and amphetamines [37]. Some of the various antimigraine drugs such as sumatriptan and zolmitriptan are cleared by MAO-A in the liver, while others are metabolized by CYP3A4 [38]. Glutathione-S-transferases (GSTs) are a major protection against reactive species generated from drug metabolites, although they do not make a large contribution to

the clearance of most drugs. They are significant in overdoses with drugs such as paracetamol.

However, several drugs, through their particular structural characteristics, are caught in other biotransformational systems that are part of endogenous molecule homeostasis and the resultant metabolites are not likely to progress excretion, as the product may be more lipophilic than the substrate. This is particularly apparent with acetylation and drugs such as isoniazid, sulfones, and sulfonamides.

1.2.7 Flavin Monooxygenases (FMOs)

These enzymes, sometimes known as the Ziegler enzymes, are found in the endoplasmic reticulum of hepatocytes as well as in the GIT. They differ from CYPs in their mechanism of action, as they transfer two electrons in one step, rather than the CYP-mediated sequential transfer of one electron after another. They tend to oxidize nitrogen- or sulfur-containing drugs, forming *N*-oxides and sulfoxides. The resultant oxidation generally increases the water solubility of xenobiotics and the FMOs overlap with and perhaps complement the CYPs in their ability to promote the clearance of a variety of drugs and toxins. The 2,4-diaminopyrimidine antiparasitic agents pyrimethamine and trimethoprim form *N*-oxides and chlorpromazine and some tricyclic antidepressants also form sulfoxides by this route. Other substrates include methimazole, clozapine, amphetamines, and tamoxifen. There are five FMO forms expressed in man; in the liver, FMO-3 is the most common in adults, followed by FMO-4, with FMO-1 expression being usually recorded as negligible [39]. The kidney, in contrast, is particularly rich in FMO-1 and to a lesser extent FMO-4, with FMO-3 expression being relatively low [40]. There is growing interest in the role of FMOs in drug metabolism, as although they are probably modulated by hormones, they are not directly inducible in man and may provide a more consistent metabolic processing effect across populations. This consistency has aroused interest in drug discovery, as it would be advantageous to develop agents with more predictable clearance routes. Interestingly, the lack of inducibility of the FMOs may not be consistent across species; recent studies have shown some element of induction in mice related to the aryl hydrocarbon receptor (AhR) cytoplasmic receptor system but not rats [41]. A lack of FMO expression is linked with the condition of “fish-odor” syndrome, where dietary trimethylamine cannot be *N*-oxidized to its odor-free metabolite [42].

1.2.8 Biotransformation and “Phase 3”

While the main components of the biotransforming system significantly alter the structure and the physicochemical characteristics of a drug and render it less lipophilic and more water soluble, there remains the problem of physical elimination of the drug-related material. Many biotransformational reactions contain some element of reversibility and metabolites can disrupt homeostasis for a variety of reasons; hence, a comprehensive system of pumps has evolved to accelerate the departure of various polar metabolites from biotransforming cells into the circulation, where they will be eventually renally filtered and cleared into urine. The MRP (also known as ABCC) pumps possess some similarities to P-gp, although they are structurally different and have evolved to exchange polar glucuronide conjugates for GSH. These can be anionic conjugates of endogenous and exogenous steroids as well as xenobiotic conjugates of

various types [43]. Unlike P-gp, the MRPs are found in the basolateral as well as apical areas of cells and their position allows them to be part of the coordinated removal of polar conjugates from the cell [44]. There are nine MRP (ABCC) genes expressed that are linked with drug-related conjugate transport and MRPs 1–5 (ABCCs 1–5) are the most documented [45]. These pump proteins are found in most tissues and these, as well as other ABC transporters are also under scrutiny for their possible role in drug resistance to epilepsy suppression, although there is little direct evidence that the main anticonvulsants are substrates for these pump systems [46]. Expression of MRP is closely coordinated with CYP and conjugation enzyme expression, and this system is extremely responsive to “load,” that is, related to drug or xenobiotic exposure.

1.2.9 Coordination of Biotransformation

Essentially, biotransformation is a flexible and adaptable system for the assembly and disassembly of vital instructional molecules, combined with a key protective function, which defends us against our chemical environment. Enormous strides have been made over the past decade in unraveling the degree of coordination between the mechanisms of detecting molecules that are to be biotransformed, their integration with biotransforming genes, the expression of the appropriate isoforms, followed by the accelerated clearance of the various oxidized and conjugated products of metabolism through to the urine and feces. The next section provides an overview of our current understanding of the ability of biotransformational systems to react to chemical challenges, from within and without.

1.3 CONTROL OF BIOTRANSFORMATION: ENZYME INDUCTION

1.3.1 Introduction

It is, of course, a prerequisite for a successful species that it can engineer major and long-term changes in its body capability as well as short-term modulations in terms of the control of small molecules such as hormones. These endogenous molecules must be part of the orchestration of puberty, as well as the maintenance of the reproductive tract, among other requirements. This needs biotransformational capacity, which can respond to changes that might range from month to month, all the way down to minute by minute.

In addition, a species must respond to threat molecules in its environment, such as changes in the chemical composition of diets, so that it can improve its long-term survival prospects. CYPs and other biotransforming systems have been subject to many evolutionary pressures, such as internal ones related to hormone assembly and breakdown, as well as by the plant toxin evolution process mentioned in Section 1.2.3.1. To endow an organism with sufficient flexibility to cover all these possibilities, some means of regulating CYP expression is essential. This fulfills two main requirements: first, that unnecessary raw materials and efforts are not deployed wastefully to express and sustain CYPs or other biotransformational systems that are inappropriate for the tasks encountered on a day-to-day basis, and second, when specific biotransforming capacity is required, it can be summoned up reasonably rapidly to cope with whatever endogenous or exogenous chemical modulating task is necessary.

Such a system ensures that an individual may respond to a chemical threat by expressing the appropriate specific and increased biotransforming capacity, which leads to a gradual increase in the clearance of the threat. If exposure to that molecule continues to increase, the system will respond commensurately, increasing to a maximal level, rather like expanding a powerful spring. In effect, the capacity to eliminate a threat molecule might increase 10- or even 20-fold in a timeframe of days to weeks. This presents problems in drug development and therapeutic applications, as it means that drug clearance is not stable until the “spring” is fully expanded and this dosage level will vary markedly between individuals. This is linked with the marked variation in background levels of particular biotransforming isoforms. Clinically, the consequences for therapy with an individual agent that acts to “induce” increased drug clearance can be complex. The drug cannot just be prescribed at a single session with a healthcare practitioner; the dose will have to be increased to keep the drug concentrations in the therapeutic window. If the patient is already taking several other agents, it is necessary to review the current regimen and take steps to determine whether the inducer will accelerate the clearance of the other agents and negatively affect efficacy. In the case of some prodrugs, this might mean accelerated production of the active agent, alongside any attendant toxicity and off-target pharmacological effects. Of course, the “spring” will snap back once the inducing drug is discontinued, which causes a marked imbalance between drug dosage and decelerating clearance to emerge over several days.

Although experienced clinical supervision is required, there are many inducers in the drug armamentarium that have been managed successfully for decades. However, vigilance is required, not least because some of the most potent inducers of biotransforming enzymes are available over the counter and patients may or may not inform their healthcare practitioner that they have decided to add these agents to their regime of their own accord.

1.3.2 CYP Induction

If, for convenience, CYPs relevant to clinical drugs are considered as four groups, then the description of the induction process can perhaps to some extent be simplified.

- Our main CYP, CYP3A4 and its close relative CYP3A5, as well as the CYP2Cs (CYP2C8, 9, and 19) and CYP2B6 could be considered in the first group. All these CYPs are responsible for the majority of prescribed drug clearance. They are inducible to a high degree and they share a similar mechanism of induction, which is coordinated through the nuclear receptor system operated by PXR.
- The second group of CYPs, CYP1A (CYP1A1 and CYP1A2) clear only a few agents, are highly inducible, but operate through the cytoplasmic/nuclear receptor aryl hydrocarbon receptor/aryl hydrocarbon receptor nuclear translocator protein (AhR/ARNT) system.
- The third group contains a single CYP, CYP2E1, which again is responsible for the clearance of only a small number of drugs, which is inducible through yet another system, which involves the proteasome.
- The final group includes just one CYP again, CYP2D6, which is not conventionally inducible at all.

1.3.2.1 Group 1: Nuclear Receptor-Mediated Induction-PXR/CAR. The respective biotransformational roles of the different CYPs to some extent inform on their modes of induction. The first group (CYPs 3A4 and the 2C series) is linked with hormone metabolism and various xenobiotics. These CYPs are controlled by nuclear receptors, mainly PXR and constitutive androstane receptor (CAR). These biosensors interact with several modulating proteins and receptors as well as through the retinoic acid X receptor (RXR) using the process of heterodimerization. The complexes thus formed migrate to various DNA response sites known as xenobiotic response elements (XREs) on the appropriate CYP gene.

The PXR nuclear receptor is also known as the steroid X receptor and nuclear receptor NR1I2. It controls CYP3A4/5 and transporter expression and appears to have become adapted to act as a xenobiotic as well as an endobiotic sensor. It is essentially expressed only “on demand” and is subject to a complex network of repressor and release proteins that are part of the mechanism that conserves and modulates the ability to respond to chemical challenges [47]. PXR itself is famously promiscuous and its large, spherical binding cavity will capture a remarkably wide structural diversity of endogenous and exogenous substrates, ranging from steroids, dozens of prescription drugs, pollutants, and dietary chemicals [48]. The major endogenous ligands that bind to PXR include bile acids and various steroids. PXR appears also to be extremely important in the prevention of cholestasis related to disorders of bile acid metabolism; indeed, PXR-mediated inducers such as rifampicin and St. John’s Wort have been shown to relieve cholestatic jaundice [49]. In humans, rifampicin is the most potent inducer and the benchmark in the drug industry for categorizing inductive potential, although there are several other potent PXR-modulating ligands (hyperforin, found in St. John’s Wort, dexamethasone, ritonavir, the organochlorine pesticide chlordane, paclitaxel, but not docetaxel), and they exert their inducing action through the subsequent binding of PXR with RXR as well as the complex array of other cobinding factors.

There is considerable evidence that the inductive effects of many chemicals are species specific and it is also related to PXR binding itself; in drug discovery, this has been addressed through the use of humanized mouse models, where human PXR has been inserted into the mouse DNA and the mouse genes deleted. This allows a PXR experimental response to inducers such as rifampicin in the concentration range seen in man [50,51]. PXR is under consideration as a therapeutic target, as there is evidence that some dietary constituents such as the sulforaphane found in broccoli can block its effects [52]. This may allow the active modulation of CYP induction in certain clinical circumstances where the resultant changes in drug levels may prejudice a successful outcome. Indeed, as mentioned previously, human CYP3A4 expression levels show very large variations [53], so the clinical impact of induction varies equally widely, as every individual’s basal expression is different.

CAR (or NR1I3) controls the induction of CYP2C9, which is probably the second most important CYP in terms of drug clearance, as well as CYP2B6. This latter CYP is emerging as being responsible for the clearance of several agents that were thought previously to be metabolized by CYP3A4, such as methadone [54]. This confusion may have arisen as it is not always possible to distinguish which CYP actually bears the main burden of a specific drug’s clearance *in vivo*, while many may metabolize it *in vitro*. The CAR receptor system differs from PXR, in that it generally operates to modulate more endogenous processes which are already strongly expressed. Another

marked difference between CAR and PXR is that there is no direct binding of an inducer to CAR itself, as the interaction appears to be linked with stabilization of the CAR complex [55]. Hence, although CAR-mediated inducers include drugs such as phenobarbitone [55], the CAR system is not as adapted to the sheer variety of xenobiotic structures that is seen with PXR, which probably reflects the narrower scope of the active site of CYP2C9 for the binding of very disparate chemical structures, which is in contrast to that of CYP3A4.

1.3.2.2 Group 2: Cytoplasmic Receptor-Mediated Induction-AhR/ARNT. The AhR is located in the cytoplasm and appears to possess several endogenous functions related to organ development and growth as well as its role in the detection of planar and lipophilic molecules such as polycyclic aromatic hydrocarbons (PAHs [56]). Of the CYPs controlled by the AhR receptor system, some prescription drugs are cleared by CYP1A1 (theophylline) and CYP1A2 (tricyclic antidepressants, R-warfarin, fluvoxamine, and clozapine), although CYP1B1 is more relevant to carcinogenesis. Of these CYPs, CYP1A1 is nonconstituent and is effectively absent unless induced by exposure to PAHs from smoking and the proton pump inhibitor omeprazole. CYP1A2 induction is sufficiently potent as a result of cigarette smoking to accelerate the clearance of agents such as clozapine and fluvoxamine to a clinically significant degree. The AhR receptor system differs from the nuclear receptors most obviously in its cytoplasmic location, where it binds its polycyclic and other substrates. It then associates with several proteins such as heat-shock protein 90, followed by complexing with ARNT [57]. The complex enters the nucleus and induces the expression of the CYP1A series and CYP1B1. This effect is seen in the liver but most notably the lung in smokers.

1.3.2.3 Group 3: CYP2E1 and the Proteasome. CYP2E1 is unusual among CYPs in that it is capable of clearing many small hydrophilic molecules, such as ethanol, pyridine, and acetone, as well as drugs such as chlorzoxazone. It is also found in somewhat unusual sites in cells, such as the mitochondrial membrane, as well as the smooth endoplasmic reticulum. CYP2E1 has long been known to be induced in alcoholism and is strongly linked with the resultant hepatic attrition [58]. CYP2E1 does not use nuclear or cytosolic receptors but is nonetheless efficiently induced by its substrates. Although the mechanism is complex, it is apparent that the substrate itself stabilizes the CYP and prevents its destruction by the proteasome; this can be illustrated in the greatly increased half-life of the CYP in the presence of the substrate [59]. That this CYP has evolved such a mechanism that is distinct from the steroid and polycyclic-oxidizing CYPs again is likely to be strongly linked with homeostasis and adaptation to environment, particularly with respect to highly specific substrates. The induction of CYP2E1 in starvation may conceivably be part of the process whereby potentially intoxicating small molecules are cleared after they result from metabolism that is adapting to severe dietary pressures [21]. That this process of adaptation to diet must necessarily be rapid to promote survival of the organism may be a corollary of the apparently somewhat wasteful continual manufacture and destruction of CYP2E1. It may also be linked with this CYP's tendency to promote oxidative stress [60]. Indeed, from a therapeutic standpoint, it is apparent that CYP2E1's major impact on humans is mainly linked with ethanol abuse rather than a significant contribution to drug clearance.

1.3.2.4 Group 4: CYP2D6 Noninduction. CYP2D6 is the only major human CYP that does not appear to undergo any form of responsive induction. Some have suggested that the evolution of this CYP is strongly linked with defense against plant alkaloids, which often have nitrogen-centered molecules which CYP2D6 appears to readily process. However, if this was the case, it is somewhat perplexing that in perhaps 100 million years, no functioning induction systems have evolved with this CYP, although some studies have reported changes in activity of CYP2D6 in response to some herbal agents [61]. Instead, there is a rather crude fixed response to the presence of multiple CYP2D6 substrates in certain environments. This takes the form of some individuals expressing many copies of the CYP2D6 gene, resulting in large amounts of functional hepatic protein. This can have marked effects on the major groups of CYP2D6 substrates, such as the antipsychotics, antidepressants, antiarrhythmics, and β -blockers, which are cleared by this CYP and the opiates (codeine, oxycodone, hydrocodone and tramadol) which must be metabolized to active opiates.

1.3.3 UGT Induction

Studies over the past decade have underlined the emerging variety of UGT substrates and the value of these isoforms in the clearance of endogenous and exogenous agents. That these isoforms are such a vital factor in human processing of such agents is underlined by the remarkable flexibility in UGT induction response. As well as its role in the control of bile acids, the primary mission of the major UGT, UGT1A1, for example, is in bilirubin conjugation. So the expression of UGT1A1 must adapt to changing bilirubin "load" to ensure that this neurotoxic hemoglobin waste product does not accumulate, so the concentration of such endogenous agents are active regulators of UGT expression. However, CYP inducers such as phenobarbitone are also potent inducers of UGT1A1 [62], and it is clear that the UGTs are regulated by many nuclear receptors, from CAR to PXR, as well as other steroid receptors and even AhR. The UGT1A1 DNA response module, known as gtPBREM, contains multiple binding sites for all these receptors. UGTs thus are sensitive to a variety of inducing drugs, ranging from steroids to rifampicin. In the past, the UGTs have been perhaps overshadowed by the CYPs; however, the advent of potent drugs, such as irinotecan (section 1.2.4), has focused clinical research on the impact of various UGTs on the efficacy and toxicity of this agent. Irinotecan exerts its efficacy through its toxic metabolite SN-38, which is cleared by UGTs, such as UGT1A1 and UGT1A7. The balance between toxicity and efficacy must be attained in each patient, despite both factors being governed by local and systemic concentrations of SN-38, which are, in turn, regulated by UGT expression.

1.3.4 SULT Induction

The mechanisms whereby the various SULTs are controlled both endogenously and exogenously are relatively poorly investigated, even in comparison with the UGTs. Indeed, for many years, they were even not recognized to be inducible. Around the end of the 1990s, it became apparent that, in animal studies, SULTs were inducible through the various nuclear receptors, although there are still few studies in human systems. However, it is emerging that the expression of some SULT isoforms are responsive to several of their main substrates. These include bile acids, peptides, steroids, and neurotransmitters, which may markedly change the expression of the major SULT

isoforms in humans [63]. The major focus of research into SULT metabolism is linked with the bioactivation of potential environmental and dietary carcinogens, rather than drug clearance. However, among these enzymes, SULT2A1 can be induced by steroids and the antifolate agent methotrexate; the latter effect is mediated through CAR, as the CAR agonist 6-(4-chlorophenyl)imidazo[2,1-b][1,3]thiazole-5-carbaldehyde O-(3,4-dichlorobenzyl)oxime (CITCO) is also effective [63]. SULT1A3, which mainly processes catecholamines, is inducible through glucocorticoids [64], while SULT1A1 is inducible through rifampicin [65]; hence, it is likely that the SULTs are controlled by the major nuclear receptors as part of the network of biotransforming enzymes and transporters.

1.3.5 Transporters

The net clinical effects of a major CYP inducer can be measured *in vivo* in terms of the increased rate of clearance of a particular probe drug, although it is much more ambitious to attempt to delineate this impact on clearance in terms of its individual components. Aside from increases in the expression of CYPs and conjugating isoforms, efflux transporters such as P-gp and influx transporters (the OATPs) and the MRPs are also induced to a powerful degree through the same nuclear receptor systems (PXR and CAR), which regulate the rest of the biotransformational response to a chemical or drug challenge. The impact of induction on these transporters is thus multifactorial, distorting the kinetics of the absorption process in the gut through P-gp, while promoting hepatic and gut uptake through the OATPs, followed by accelerated clearance by the induced CYPs to greater quantities of polar metabolites, which, in turn, are cleared more rapidly toward bile and urine. It is likely the most relevant *in vivo* analysis concerning transporter induction and its impact on drug flux is probably best obtained from cellular models [66].

1.3.6 Coordination of Biotransformational Induction: Receptor Cross-Talk

As outlined earlier, the induction of biotransformation requires a coordinated response to the agent, which involves the transporters, CYPs, conjugation isoforms, and MRPs, not to mention the increased expression of cellular protective systems such as the GSTs, which are of greatest relevance in detoxification rather than prescription drug clearance. There is now a great deal of evidence that the various nuclear receptors as well as the cytosolic AhR all act in concert to ensure that every stage of biotransformation is managed to promote not only clearance in the sense that a drug is converted to a less pharmacologically potent metabolite but also physical removal into the urine and the feces. All the major biotransforming enzyme systems as described above have DNA response elements that are responsive to PXR, CAR, and the glucocorticoid receptor (GR). It is known that the nuclear receptors PXR and CAR are regulated by and in turn regulate AhR [67]. These receptors are, in turn, controlled by a “senior” hierarchy of the hepatocyte nuclear factors (HNFs), such as HNF1 α and HNF4 α . HNF1 α regulates a large number of genes linked with glucose, lipid, and protein metabolism and controls the transcription of UGTs after the PXR/RXR system has been activated [68]. HNF4 α acts to transcriptionally regulate CYPs in a similar way and is one of the means by which the various nuclear receptors’ inductive effects are coordinated across a biotransforming tissue and organ [69]. CYPs and other

biotransforming systems are also cross-regulated by numerous transcription factors, such as nuclear factor kappa B (NFκB) [70]. This complex and multifactorial transcriptional regulation system allows living organisms the ability to regulate their own homeostatic processes, while simultaneously protecting themselves from dietary and environmental chemical assaults. Unfortunately, in terms of drug therapy, this well-organized, sensitive, and highly effective system is a formidable obstacle to successful and stable therapeutic intervention and is capable of not only undermining but effectively abolishing drug effect through rapid clearance. It is also less well appreciated that the process of enzyme induction where prodrugs are concerned can lead to excessive adverse reactions and off-target pharmacological effects. To compound this therapeutic hazard, some prescribed agents, such as rifampicin, will accelerate the clearance of a very wide range of drugs cleared by the major CYPs as described previously but also over-the-counter (OTC) medicines can cause this effect also, sometimes as mentioned previously, without the knowledge of prescribers.

1.3.7 Induction: Clinical Consequences

There are many clinical examples of drug interactions that are based on the effect of inducers. Indeed, although this effect is highly undesirable in drug development, a recent study has nonetheless shown that just under half currently used prescription drugs have some inductive capability [71,72]. In terms of therapeutics, the effects of induction could be classified as either expected or unexpected. When a known inducer is deliberately added to a regime, the effects can be anticipated in terms of titrating the increased dosage over a period of time that will be, in effect, customized according to the patient. This requires a considerable measure of clinical input and experience to accomplish while maintaining continuity of clinical care, through continuity of drug concentrations within the therapeutic window. When an inducer is added to a drug regime without the knowledge of the various prescribers who have care of the patient, either by another prescriber or by the patient's initiative, the effects may go unnoticed until failure of drug therapy results or if excessive metabolite production results in toxicity.

As far as anticipated inducers are concerned, rifampicin will induce most of the main CYPs, such as CYP2B6 and CYP2C8/9/19, as well as CYP3A4/5, so accelerating the clearances of hundreds of currently used drugs, including agents such as losartan, propranolol, and verapamil, which can effectively remove their therapeutic effects [71]. Anecdotal evidence suggests that rifampicin is sometimes used in terminal patient care to eliminate multidrug-resistant *Staphylococcus aureus* (MRSA) infections and this can accelerate the clearance of previously stabilized opiate regimes, such as with methadone, requiring major skilled adjustment in dosage. The first generation anticonvulsants such as phenobarbitone, carbamazepine, and phenytoin as well as steroids such as dexamethasone show a broadly similar impact on CYP capability. Other inducers that have a less potent effect on CYP3A4 include the various protease inhibitors (ritonavir and nelfinavir) and the nonnuclear reverse transcriptase inhibitors, such as efavirenz and nevirapine. Most clinicians are aware of the potency of these inducers to cause coadministered drugs to fail to maintain adequate plasma levels and dosage adjustment is essential to maintain therapeutic effects.

Other inducers are less easily detected, as their effects are variable and they are within the realms of patient lifestyle choices. Patients will usually admit to smoking, although they may not divulge the full extent of their tobacco intake, in the same

way that many are somewhat reticent about their ethanol intake also. The inductive effects of smoking really only concern a small number of drugs that are cleared either partly or wholly by CYP1A2, such as clozapine, fluvoxamine, and warfarin [73]. If an individual smoking habit is stable, then they will already be induced to an equally stable extent in terms of their CYP1A2 expression. Hence, whichever dosage is arrived at based on clinical response should not be affected provided they continue to smoke. Of course, patients are exhorted constantly by their families as well as their healthcare practitioners to try to cease or even just reduce their smoking, and although this is desirable for the patient's health, it is important that they are counseled to inform their prescribers when or if their smoking status changes, as a loss of the inductive effect will cause a "smoking" dosage regime resulting in drug accumulation, with a commensurate impact on off-target effects, toxicity, and ultimately patient tolerance.

One of the most powerful inducers of CYP3A4 and P-gp is St. John's Wort, which is available OTC and, as with all herbal preparations, varies enormously in its relative potency. This agent is now known to have clinical effect which is certainly no worse than many prescribed antidepressants and many individuals under treatment for major conditions such as HIV, cancer, or xenograft recipients are likely to become depressed and might resort to St. John's Wort or similar OTC remedies. The potency of this herb is underlined in instances where it has accelerated the clearance of immunosuppressives such as cyclosporine to the point that xenograft rejection has occurred [74]. St. John's Wort also reduces the efficacy of irinotecan, by lowering the plasma concentrations of SN-38, the active metabolite [75], and it also accelerates the disappearance of imatinib, the tyrosine kinase inhibitor used in the treatment of chronic myeloid leukemias [76]. The herb can cause marked adverse reactions in the case of agents such as cyclophosphamide, which rely on CYP-mediated activation to a reactive and toxic metabolite. When the activation process is responsible for both clinical effect and toxicity, a marked shift in toxic metabolite formation may tip the balance toward unacceptable patient toxicity. The key clinical problems with St. John's Wort include its variability in potency and speed of inductive effect as well as the likelihood that patients may not feel that they should inform their healthcare practitioners that they are self-medicating.

Interestingly, recent studies *in vitro* have shown that several anticancer agents, such as ifosfamide, cyclophosphamide, and paclitaxel, are capable of activating PXR and may cause some measure of induction in patients, although this is not always detectable clinically due to the coadministration of inducers during therapy such as steroids [77]. Some studies with higher doses of cyclophosphamide have reported increased elimination that may be linked with autoinduction of metabolism, as this agent is oxidized by several inducible CYPs, including CYP3A4, CYP2B6, and CYP2C19 [78].

Overall, it is apparent that many compounds do bind to PXR, but relatively few agents exert a clinically relevant inductive effect, although those that do present many problems to the day-to-day clinical management of disease states.

1.4 PHARMACOGENETICS: IMPACT ON DRUG EFFICACY

1.4.1 Introduction

It is clear that the success of our species is strongly linked with our genetic variability, which promotes our adaptability, which extends to our biotransformational capabilities.

Although the first studies in this area began with isoniazid in the 1950s and extensive work followed with enzymes such as CYP2D6 and thiopurine-S-methyltransferase (TMPT) from the 1980s onward, the full extent of the pharmacogenetic variation in human biotransformation is still not fully understood. A genetic polymorphism is taken as significant when it affects more than 1% of any given human population and such polymorphisms are usually, but not always, linked with reduced or absent capability in a particular enzyme. The defects can range from specific point mutations leading to the substitution of a critical amino acid for a disadvantageous one which is at or near the active site of the enzyme, to TATA box defects where gene promoters are misread, leading to poorly functional protein. These traits are retained in populations, as they may confer advantage that may ensure the survival of a species if the wild-type, that is, the majority of phenotypes, are adversely affected by a toxin that might require bioactivation, for example. Although polymorphisms benefit species survival, they may be a severe handicap for the individual. The extent of this handicap is related to whether the individual possesses more than one defective allele or copy of the particular gene.

The “wild-type” allele is usually designated *1, followed by those for the various defective alleles, which may be designated *2, *3, and so on. In the case of CYP2C19, the wild-type is quoted as CYP2C19*1, and this allele is fully functional. As one allele is received from each parent, a *1/*1 homozygous individual has full CYP2C19 expression and catalytic activity, so this person would be classed as an extensive metabolizer (EM). Individuals who possess at least one copy of the *2 or *3 alleles together with a copy of the wild-type *1 allele will have reduced expression, such as CYP2C19*1/*2 or CYP2C19*1/*3. These heterozygotes are termed intermediate metabolizers or IMs. Homozygous poor metabolizers (PMs), such as CYP2C19*2/*2, would be termed PMs and would have little or no expression of competent isoform [17]. With many CYPs, there are also small populations where individuals express several copies of the same gene, leading to rapid metabolism with CYP2D6 or there are also ultrarapid alleles, where the CYP is unusually fast metabolizing. With CYP2C19, this is termed *17 and a homozygote for *17 would metabolize a substrate many times more rapidly than the wild-type individuals. Although there are considerable numbers of studies that might quote frequencies of allele appearance in populations, the frequencies of homozygous and heterozygous individuals are the main concerns, as this describes drug clearance capacity in a single individual for a particular isoform.

1.4.2 Pharmacogenetics and Drug Development

As CYPs and other biotransforming systems process more than 80% of drugs in some form or other, population distributions of a particular CYP, for example, have taken on enormous significance in the light of global drug development and marketing. The economic pressures behind modern drug development are such that only such universal marketing may allow a commercial entity sufficient return on the admittedly vast investments necessary to propel a drug to the clinic. However, the lack of homogeneity in human biotransformation is a serious impediment in this global drug marketing drive. If a drug is not cleared by a substantial patient subpopulation, this will promote concentration-dependent toxicity and off-target effects that will reduce patient tolerance. Conversely, if a drug requires metabolic activation before the achievement of clinical effect, then if a population of individuals cannot activate the drug, it will fail to provide therapeutic care and other agents will be substituted.

A key issue is how this information is actually discovered. While many thousands of studies have been published on the huge numbers of individual CYP alleles that can be identified using molecular biological techniques using patient blood samples, there are only comparatively a tiny number of clinical studies on human polymorphisms that actually study the real-life consequences in terms of drug toxicity or failure [79]. Indeed, the numbers of individuals in these studies are minuscule when compared with those routinely included in phase II and III trials for new drugs. Given that many new drugs have been evaluated in anything up to 8000 patients before licensing and still must occasionally be withdrawn due to toxicity, it is clear that a greater emphasis on future clinical work is required to provide the necessary data for predictions on the consequences of biotransformational polymorphisms in human populations.

1.4.3 Biotransformational Polymorphisms

1.4.3.1 NADPH Oxidoreductase. The catalytical activity of CYPs is powered by electrons that are supplied by cytochrome *b*₅ and P450 NADPH oxidoreductase (POR). POR is vital to many processes, but individuals with Antley–Bixler syndrome do have reduced efficiency POR, which can, in turn, compromise CYP3A4 activity and their steroid metabolism [80]. Fortunately, POR polymorphisms appear to be very rare and are not really clinically relevant.

1.4.3.2 CYP3A. Although CYP3A4 clears the majority of prescription drugs, it is generally not subject to significant polymorphic expression, although there has been a report on possible differences between Chinese individuals and Caucasians in terms of CYP3A4 expression, where simvastatin clearance was reduced and its therapeutic effect was commensurately increased [81]. Indeed, along with many other drugs, it is recommended that patients of Chinese extraction and other Eastern races should be at least be started on lower doses of statins due to their general reduced capacity for drug clearance [82]. CYP3A4's close relative CYP3A5 is found in Afro-Caribbean populations and is polymorphic [83].

1.4.3.3 CYP2C9. CYP2C9 is of intense interest, as it accounts for just under a fifth of total hepatic CYPs and is responsible for the clearance of warfarin, several NSAIDs, phenytoin, and many other agents [84]. The major allelic variants of CYP2C9 are the wild-type *1 as well as the defective alleles *2 and *3. The *2 variant is found in 10–13% of Caucasians, while *3 is less common, at around 5–9%; Chinese and Africans have lower frequencies of these alleles [84]. The *2 and *3 variants of CYP2C9 are much less catalytically efficient than the wild-type [85] and this leads to an inability to clear standard doses of anticoagulants, causing excessive bleeding [86]. Interestingly, one particular heterozygous CYP2C9 combination (*1/*3) is strongly linked with males; hence, it is possible that more polymorphisms remain to be discovered which are sex linked [87]. It is often noted that many CYP2C9 substrates have relatively narrow therapeutic indices, so making some investigation into genotype before therapeutic intervention is more desirable to reduce toxicity.

1.4.3.4 CYP2C19. This CYP, formally known as mephenytoin oxidase, has assumed increased importance in recent years, primarily related to its metabolism of several highly successful drugs, including the antiplatelet agent clopidogrel as well as the

proton pump inhibitors. This CYP is also interesting, as aside from its wild-type allele, its two major polymorphic forms (mentioned already in Section 1.4.1) include *2 (more common in Caucasians) and *3, are both nonfunctional. The *3 allele is found in more than 10% of Chinese, but it is rare in other races [84]. Overall, PMs (*2 or *3 homozygotes) of Chinese extraction of this CYP are more common (up to 23%) than in Caucasians (12–23%) and lowest in Africans (4–8%) [88,89]. Consequently, impaired activity of CYP2C19 actually promotes the efficacy of the proton pump inhibitors, while it reduces the efficacy of the anticancer agent cyclophosphamide, as insufficient active metabolite is formed in homozygous CYP2C19*2 individuals [90]. It has also been suggested that CYP2C19 deficiency impairs the efficacy of clopidogrel, which requires metabolism (although several CYPs can activate it) to its active thiol to show efficacy [91]. However, CYP2C19 loss of function has not been shown to significantly impair Caucasian and Latin American patient response in a study with clopidogrel [92], but in another study, CYP2C19 and P-gp status did affect the drug's response [93]. It is probable that the argument will be settled with either prasugrel, which is a relative of clopidogrel and can be activated by many biotransforming systems, or a directly acting agent such as ticagrelor. This latter drug neatly circumvents the polymorphic biotransformational issues and may be more cost effective over its lifetime compared with clopidogrel, as genetic testing is not required for its maximum efficacy [91].

1.4.3.5 CYP2D6. This CYP figures in the clearance of several important groups of drugs, such as the antipsychotics, several antiarrhythmics, and SSRIs as well as the activation of a number of opiates to derivatives that demonstrate morphine-like actions. Thus, CYP2D6 has been the most exhaustively investigated polymorphic CYP and homozygotes for the *4 allele show little or no functional enzyme [94]. In Caucasians, as many as 10% may carry two *4 alleles, which may amount to perhaps 60 million individuals worldwide, although only around 1% of Africans and the Eastern races display this genotype. There is also a deleted gene variant (*5), which is also found in most populations at around 3–5% [95]. It is divided as to whether the PM status actually leads to severe problems in individuals during therapy with certain drugs. It is clear that CYP2D6 is required for optimum activity from tamoxifen, as this prodrug requires activation to potent estrogen antagonists [96]. Other studies have shown that tricyclic antidepressants may show increased toxicity in CYP2D6 PMs [97]. Interestingly, a study that evaluated the effect of PM status on the opiate-like effects of tramadol indicated that despite the lack of CYP2D6 activity, PMs could derive analgesia from the drug [98]. Hence, other CYPs and biotransforming systems, along with additional pharmacological effects with various drugs, may compensate for a lack of metabolism to active agents in *4 and *5 homozygotes.

Individuals with multiple copies of CYP2D6 can clear its substrates extremely rapidly, with opiate toxicity resulting in the case of codeine [95]. It is clear that there are far more studies identifying potentially defective CYP2D6 alleles than are those clinical studies that firmly indicate that PM status predisposes to toxicity and conversely or that PM status abolishes prodrug activation. The significance of CYP2D6 lies mainly in the sheer numbers involved, particularly in the developed world, where therapeutic drug use is more likely than in other populations.

1.4.3.6 Other CYPs—CYP2C8 and CYP2B6. CYP2C8 is mainly known for its metabolism of NSAIDs such as ibuprofen as well as the anticancer agent docetaxel.

Although induction of CYP2C8 is linked with accelerated docetaxel clearance, there appears to be much less of a link between CYP2C8 status and docetaxel clearance or toxicity [99–101]. CYP2B6 is extremely variable and polymorphic [102] and the *6 variant is the commonest defective allele, with only a quarter of the wild-type expression [103]. As touched on earlier, the role of CYP2B6 is gradually emerging in the case of several drugs, such as methadone, which were thought to be cleared by almost entirely by CYP3A4 [54,104]. This is probably linked with studies where known inducers such as rifampicin-caused accelerated methadone clearance and it was assumed that this would be CYP3A4, although most of the PXR/CAR inducers induce all the CYP2Cs, CYP2B6, and the CYP3As. CYP2B6 polymorphisms are associated with altered metabolism in several drugs [105,106] and it is likely that the impact of CYP2B6 polymorphisms on drug toxicity and efficacy is far from full elucidation.

1.4.3.7 FMO Polymorphisms. The major FMO that forms drug-related *N*-oxides in man is hepatic FMO-3, which is subject to a large number of different poorly functional and nonfunctional polymorphic forms, which make up the 1% or so of individuals in Caucasian populations who have trimethylaminuria. These individuals cannot clear trimethylamine to an odorless *N*-oxide and consequently their breath and perspiration smells strongly of fish. Owing to its lack of induction and high capacity, FMO-3 has been considered as a useful clearance route for drugs such as the gastroprokinetic agent itopride, which is free of the problems associated with cisapride. The latter agent was cleared by CYP3A4 and inhibition of this CYP resulted in cardiotoxicity [107]. While FMO-3 polymorphisms do exist, they appear to occur at a lower rate in comparison to other CYPs, such as CYP2D6, so this may be a promising area in drug development. An agent cleared by FMO-3 would not be subject to accumulation except in a small proportion of individuals and the lack of enzyme induction would also be highly desirable, in terms of cost savings in therapeutic monitoring.

1.4.3.8 UGT Polymorphisms. The most significant UGT polymorphism is the TATA box promoter error known as Gilbert's syndrome; this is associated with the allele UGT1A1*28. UGT1A1 is the only known conjugative pathway for bilirubin, which is a neurotoxic metabolite of hemoglobin; so homozygotes for this allele have only about a third of the wild-type capability in clearing this agent. As with other polymorphisms, such as glucose-6-phosphate dehydrogenase deficiency, this can just about be tolerated and does not cause liver damage. However, it does predispose to some cancer risks (related to poor clearance of estrogens) and reduce others [108,109] as well as providing some protection in heart disease due to the antioxidant effects of the mild hyperbilirubinemia that results with this polymorphism [110]. As there is relatively little margin in conjugative capacity in Gilbert's syndrome, it has been established that drugs such as protease inhibitors that are capable of UGT1A1 inhibition can cause marked hyperbilirubemias [111]. Probably the best-known drug toxicity issue with Gilbert's syndrome is in irinotecan therapy, where the active SN-38 metabolite is not cleared due to lack of UGT1A1 expression and toxicity results; there is evidence that other UGT polymorphisms are linked with Gilbert's syndrome, such as UGT1A7 (section 1.2.4), which also markedly affects the toxicity linked with irinotecan therapy [112]. Unfortunately, as SN-38 is responsible for the toxicity as well as the activity against the cancer, so the potential for a strong therapeutic response may rest on the patient's tolerance to the toxicity. There are complex differences in UGT1A1 and other UGT

isoforms across ethnic populations that can lead to significant variation in susceptibility to drug toxicity where UGTs are a primary biotransformational pathway [113].

1.4.3.9 *SULT Polymorphisms.* As mentioned previously, the biotransformational capacity of the SULTs is of interest from the standpoint of predisposition to certain cancers as well as for drug clearance. This is due to the tendency of some of the SULTs, such as SULT1A1, to clear phenolic agents such as not only paracetamol, but also various aromatic amines that can be bioactivated. These agents can attack DNA and lead to malignancy [114]. SULT1A1*2 and *3 are less catalytically competent and stable [115]; hence, expression of SULTs may strongly influence predisposition to certain cancers. There is also evidence that SULT1A1 genotype may influence the effectiveness of tamoxifen, as the *2 variants may negatively affect patient survival, as sulfonation of the drug's hydroxylated metabolites improves its potency [115–117].

1.4.3.10 *Other Biotransformational Polymorphisms.* There are several other biotransformational systems that are polymorphic and have some bearing on the clearance of prescription drugs. Microsomal epoxide hydrolase exists in several catalytic forms and is thought to have bearing on the antiepileptic agent carbamazepine, which is cleared by CYP3A4 to a 10,11-epoxide, which retains pharmacological activity, although it is responsible for some toxicity. More catalytically rapid versions of epoxide hydrolase (such as Arg139) will reduce the therapeutic effect of the drug by clearing the epoxide to a diol, which is not active, while slower versions (such as 113His) run at about half the velocity of the wild-type and will have the reverse effect, possibly increasing toxicity [118,119]. The toxicity of azathioprine is strongly linked with TMPT status, an enzyme that clears the toxic purine metabolites, which confer the activity on the drug. There is evidence that the TMPT phenotype, as detected through a simple functional blood assay, is much more relevant than genotype. This is partly due to concomitant therapy in leukemias where inhibiting salicylates are also used.

1.4.4 Pharmacogenetic Testing: The Future?

1.4.4.1 *Introduction.* There are now several commercially available test systems that can be used to determine genotype in some biotransforming enzyme systems. While this technology is developing rapidly, in terms of reductions in costs as well as sample volumes, the use of these tests has not yet become accepted or widespread in developed countries with the resources to afford them. This is rather surprising in the context of the acknowledged desire of future medicine to become more customized to the patient's individual needs. There are many possible reasons for this and some are discussed below.

1.4.4.2 *Mass or Niche Therapy?* The benefits of pharmacogenetic testing should, in an ideal world, be considered solely in terms of clinical merit. The aim should be to optimize drug therapy to minimize toxicity and maximize drug performance and tolerance. However, cost issues have become increasingly intrusive in drug therapy in general, particularly in the UK, where new drugs are evaluated in terms of efficacy and value for money by the National Institute for Clinical Excellence (NICE). Some authors have analyzed the cost/benefit ratios of certain pharmacogenetic tests and found that several are probably an unattainable luxury [79]. In addition, clinicians

can be reluctant to adopt new tests, partly due to expense and partly due to uncertainty over how to interpret the results. This is borne out by studies which have underlined that CYP2C9 status is not the only contributor to warfarin variability of response and vitamin K epoxide reductase complex subunit 1 (VKORC1) status must also be determined [120]. It is likely that many other tests available currently are also only a single piece in the puzzle as to why a particular drug shows an aberrant effect in an individual or a group of patients. While irinotecan packaging is labeled with warnings linked with the risks of UGT1A1*28 status, the expression of other isoforms, such as UGT1A7, is also a vital component of any patient's response. Similarly, the respective expressions of several genes have a strong impact on tamoxifen therapy, and optimization based on a series of pharmacogenetic tests could markedly improve the efficacy of this agent.

Until our knowledge of all the conflicting haplotypes and their impact on the clearance of a particular drug is understood, many of the recommendations currently given may be somewhat incomplete and it is probably not unreasonable for clinicians to be wary of basing important therapeutic decisions on these data.

There is also the question of whether pharmacogenetic testing would make a cost-effective contribution of niche areas, where small groups of drugs are deployed in a relatively specialized patient population, which is already under close clinical supervision. Such areas include the use of antipsychotics, anticoagulant, and antineoplastic therapy. In the case of sudden death during antipsychotic use, it has been suggested that this is linked to TdP, caused by CYP2D6 polymorphisms. The failure to clear the drugs may have led to sustained high levels in PMs, which, in turn, caused cardiotoxicity. However, recent studies suggest that sudden death in these patients is dose related, but importantly, it is independent of whether older CYP2D6-cleared or newer, non-CYP2D6-cleared agents are used [121]. Hence, although theoretically, some benefit for pharmacogenetic testing of CYP2D6 status should exist, it is likely that other factors are involved in the predisposition of some patients to increased risk of cardiotoxicity. So it is difficult to assess genotypic testing would be of benefit to the experienced clinician. In addition, with drugs used in intractable pain relief in terminal care, such as methadone, the complexity of this drug's clearance may depend on several factors other than CYP2B6 status and to date, caution in escalating the dose may well be just as adequate as knowledge of CYP expression status [122,123].

Anticoagulant therapy as stated previously is linked with VKORC1 as well as CYP2C9 status and in any case, warfarin is monitored pharmacodynamically with great care already and it is possible that genotyping may not be of great benefit when doses are carefully titrated routinely during the initiation of therapy. Anticancer therapy is already closely clinically monitored, with individual patient response assessed for toxicity and efficacy during treatment cycles, although sadly, there is evidence that despite the availability of TMPT status determination for some years, more than 86% of deficient individuals still develop azathioprine-mediated myelosuppression [124].

1.4.4.3 Future Perspectives. Two other issues are relevant in pharmacogenetic testing. With TMPT, the value of a phenotypic test over a genotype test suggests that in many other polymorphisms, it may be misleading or even counterproductive to rely on genotypic testing to make major decisions over therapy. There may be no substitute for an accurate functional determination of the individual's biotransformational activity with a particular drug. In addition, there are also issues relating to investment in pharmacogenetic tests, which may be somewhat hazardous commercially, given that a

rival organization may be on the verge of marketing a radical alternative drug, which does not require any testing to maximize its potency, such as the case of clopidogrel, prasugrel and ticagrelor.

Pharmacogenetic testing hopefully should become more economical and better incorporated into hospital routines, which should be accompanied with a growth in clinical knowledge, experience and the development of relevant standard operating procedures. In time, as more is understood about all the various gene expressions involved in individual drug/patient responses, pharmacogenetic testing of biotransforming enzymes may be of benefit particularly during the initialization of therapy, where it could prevent marked over- and underprescribing, linked to patient variation in biotransformational response.

1.5 INHIBITION OF DRUG BIOTRANSFORMATION: CLINICAL CONSEQUENCES

1.5.1 Introduction

Inhibition of drug metabolism probably poses the greatest physical risk of harm to the patient from several perspectives:

- Unlike the process of induction, the biotransforming system is usually unable to adapt to the inhibition. While the induction process is adaptive, inhibition is similar to blocking the exhaust pipe of the engine of a motor vehicle—it cannot adapt and it just stops. If other pathways are capable of clearing the excess drug, they may well not have the capacity of the main inhibited pathway. While some adaptation might occur eventually, drug accumulation will probably happen much more rapidly, indeed within hours, leading to several potential outcomes. These include major intensification of the pharmacological effect of the agent, as well as off-target effects, followed by frank toxicity if drug levels continue to increase.
- Drugs that already have very high or high first pass will be particularly vulnerable to inhibitors and plasma levels can increase dramatically. Agents such as simvastatin, lovastatin, nimodipine, felodipine, and tacrolimus are good examples.
- The consequences of drug accumulation in narrow therapeutic index drugs can be extremely severe and clinical problems may begin within a very short timeframe, potentially within 2–3 h of drug dosage in some cases.
- If an inhibitor is added to a polypharmaceutical regime, it may retard the clearance of more than one of the drugs in the regime, leading to a complex series of pharmacological and toxicological effects, which may or may not be synergistic.
- Issues related to the practitioner and their knowledge of the patient are also relevant. The prescribing practitioner may not be aware of the inhibitory effects and how rapidly they may overtake the patient. In today's environment of multiple prescribers, one prescriber may not necessarily be fully aware of the patient's regime.
- If the patient ingests a dietary inhibitor, the practitioner will almost certainly not be aware of the developing situation and of course, neither will the patient.

- The usual caution that might govern clinical dosage recommendations, may not necessarily apply when a patient is already subject to a polypharmaceutical regime and just “one more” drug is added to this regime.

All these factors may cause severe injury to the patient in a relatively short time. The main clinical issues of drug inhibition are effectively the intensity, duration, and reversibility of the inhibitor’s effect as well as the specific pharmacological and toxicological impact of the inhibited drug, or drugs, on the patient.

1.5.2 Major Clinically Relevant CYP Inhibitors

1.5.2.1 Reversible Inhibitors: Azoles. Over the past 30 years, successful transplant therapy, from stem cells to complete organs, has been made possible through immunosuppressant drugs, which, in turn has led to major problems in the control of opportunistic fungal disease. The azole drugs have been extremely important in fungal elimination, as alternative drugs such as amphotericin B are much too toxic [125]. All the various azole derivatives, dating from the earliest such as ketoconazole through to more modern agents like such as fluconazole, voriconazole, and posiconazole, are all reversible inhibitors of human CYPs to varying degrees. This is hardly surprising because they were designed as CYP inhibitors of yeasts, blocking 14 α -lanosterol demethylase and leading to toxic accumulation of 14 α -methylated sterols, although they generate reactive species that are also damaging to the yeasts [126]. Their lone pair of electrons in the heterocyclic nitrogen group inhibits through a form of NADPH-mediated, reversible association [127].

The most potent of this class in terms of CYP inhibition is the now obsolete ketoconazole, followed by itraconazole and voriconazole, then fluconazole; these agents tend to inhibit CYP3A4, CYP2C9, and CYP2C19 and their propensity for drug interactions is very high, up to 70% [128]. Interestingly, posaconazole only inhibits CYP3A4 and its inhibitory capacity is not fully elucidated clinically. Voriconazole is cleared by all the CYPs it can inhibit, while the others are less extensively metabolized by CYPs with posaconazole undergoing clearance by UGTs. Itraconazole and posaconazole are also P-gp inhibitors.

The main problem with these drugs is that the major immunosuppressants, cyclosporine, tacrolimus, and sirolimus are all CYP3A4 substrates and when the azoles are used to treat fungal infections, there is potential for accumulation of the immunosuppressants with concomitant organ damage and neurotoxicity [129]. This effect varies according to the azole and the immunosuppressant; with tacrolimus, drug levels must be reduced by 40% to prevent toxicity in the presence of fluconazole [130], while ketoconazole requires a 70% reduction in cyclosporine dosage; indeed, it was proposed that this might be beneficial in reducing the dosage of cyclosporine and making the drug more economical to use [131]. While the ethics of such an approach are questionable, there is a necessity to reduce the dose of cyclosporine and other immunosuppressives during azole therapy to prevent toxicity and the beneficial byproduct is a temporary reduction in the usage and therefore the costs of the immunosuppressants [129,132]. However, extended use of the azoles, as with many other anti-infectives, promotes resistance and it is not ethically or scientifically reasonable to use these drugs to reduce the costs of immunosuppressant therapy [133].

Azoles may interact with many other drugs cleared by CYP3A4, CYP2C19, and CYP2C9. For example, benzodiazepines' sedative effect is greatly enhanced [134] and the CYP3A4-cleared statins may cause rhabdomyolysis in the presence of azoles. There are many drugs that are CYP3A4 substrates that are capable of causing life-threatening TdP and concomitant azole therapy could cause sudden death in such situations.

It is worth noting that despite their ability to inhibit CYPs, azoles are as vulnerable as many other agents are to potent enzyme inducers, particularly the more extensively metabolized drugs such as itraconazole and voriconazole [135,136].

1.5.2.2 Irreversible Inhibitors: Grapefruit Juice. Any part of grapefruit, whether it is tinned, diced, fresh, preserved, or juiced can inhibit CYP3A4 metabolism [11]. While reversible inhibitors such as the azoles may be overcome by substrate, the mechanism-based inhibitors such as grapefruit juice exert a more long-lasting effect, which may continue for up to a week after the last consumption of the juice [137]. It is easy to see that habitual consumption of the juice will virtually shut down the CYP3A4 activity in the gut and as this CYP accounts for the majority of gut CYP activity, this effectively cripples gut drug oxidation; indeed, hepatic CYP3A4 is also inhibited if the juice dosage is sustained and large enough [138]. The inhibition of CYP3A4 appears to inactivate the isoform and necessitate the synthesis of new enzyme and several chemical constituents of the fruit accomplish this. These include various furanocoumarins, such as the bergamottin derivatives, and it is thought that any of these agents will act as inhibitors of CYP3A4 if they contain the 5-geranyloxyfurocoumarin group [139]. The effects of the juice are made more complex by a mild inhibition of P-gp as well as a more potent effect on the OATPs. Overall, grapefruit, Seville orange, pomelos (a grapefruit relative), and other citrus fruits exert complex effects, as they decrease bioavailability through OATP inhibition with drugs such as fexofenadine, as well as inhibiting CYP3A4 clearance and inhibiting P-gp, thus increasing bioavailability [140,141]. The best-documented and severe consequence of grapefruit-mediated CYP3A4 inhibition is fatal TdP from terfenadine accumulation [142]. Statin accumulation and subsequent rhabdomyolysis is also a risk of grapefruit juice ingestion as well as increased bioavailability of felodipine.

1.5.2.3 Other Irreversible Inhibitors. There are many other agents that can act as irreversible inhibitors of CYPs, such as the macrolides erythromycin and clarithromycin [143], the SSRIs fluoxetine, paroxetine and fluvoxamine (particularly CYP2D6) as well as several anti-HIV drugs such as ritonavir and delavirdine and the calcium channel blockers verapamil and diltiazem [144]. Inhibitors often have complex clearance pathways themselves, aside from their effects on other drugs. The antiarrhythmic amiodarone is extensively cleared by CYP3A4, as well as CYP2C8, but it is a mechanism-based inhibitor of CYP3A4 and several other CYPs. Amiodarone can markedly affect clozapine and warfarin clearance [145,146], although its own clearance is also acutely vulnerable to inhibition by grapefruit juice [147]. Illicit agents such as 3,4-methylenedioxymethamphetamine (MDMA; a.k.a, ecstasy) probably make a markedly underestimated impact on patient health through CYP inhibition. The protease inhibitor ritonavir has caused fatal accumulation of MDMA [148], probably through CYP2D6 inhibition, while MDMA itself is a mechanism-based inhibitor of CYP2D6, possibly exerting its effects for up to 10 days [149].

Unfortunately, potent mechanistic inhibitors of CYPs are still appearing in the medical armamentarium, such as the relatively new anticancer agent lapatinib, which is a mechanism-based inhibitor of CYP3A4 and has also caused fatal hepatotoxicity [150]. In general, CYP inhibition, particularly of the major isoforms such as CYP3A4, can jeopardize the future of a new drug, unless it has little or no competition in its therapeutic area. Certainly, one of the contributory factors in the withdrawal of Serzone (nefazodone) was its potent inhibition of CYP3A4, making it difficult to add to existing polypharmaceutical regimes as well as its hepatotoxicity.

1.5.3 Relevant Conjugative Inhibitors

1.5.3.1 UGT Inhibition. There is generally less attention paid to inhibition of conjugative processes rather than CYP inhibition. There are, however, several agents that are capable of inhibiting UGTs, such as ketoconazole, which inhibits UGT1A1 and UGT1A9; ketoconazole can increase SN-38 levels by inhibiting UGT1A1 during irinotecan therapy. The drug can also block lorazepam and AZT glucuronidation, through inhibition of UGT2B7 [151]. The insulin secretagogue repaglinide's glucuronidation is inhibited by gemfibrozil, which is a UGT1A1 inhibitor [152]

1.5.3.2 Sulfonation Inhibitors. The NSAIDs mefenamic and salicylic acids can inhibit sulfonation to a clinically relevant degree [153], while several dietary flavonoids and phytoestrogens are potent inhibitors of sulfonation as well as genistein [154]. Generally, most agents that might be cleared through sulfation would be likely to be cleared through other pathways which would be able to act to remove any accumulation. Hence, sulfation inhibition is more likely to be relevant to carcinogenesis, rather than drug clearance.

1.5.4 Clinical Relevance of Inhibition

1.5.4.1 Introduction. The major feature of CYP inhibition in particular, is how quickly the inhibitor, regardless of its mechanism, can arrest CYP processing. If a drug depends on a particular CYP for clearance, the problem will develop more rapidly than with agents that may be cleared by several independent processes. The inhibition process may occur in less than a few hours, which is in stark contrast to induction, which is measured in days and weeks. The rapid accumulation of the drug or drugs will then expose the patient to a double jeopardy; the drug's specific on- and off-target pharmacological effects, plus they are also likely to be away from medical attention, having just collected their medication and probably returned to their homes or work. The accumulation-driven drug effects will quickly move toward toxicity and factors such as the dosage and the individual target of the drug's effects will govern the degree of toxicity encountered. Some major clinical consequences of toxicity are described below.

1.5.4.2 Torsades des Pointes (TdP). This particular problem is probably the key concern of any drug development programme, in terms of risk of toxicity, as this condition can lead to death in a few hours. Surprisingly, there are dozens of drugs that can cause TdP, although it is usually acutely dose dependent [155], so in everyday drug usage, the risk should theoretically be relatively low. The problem arises due

to myocardial human ether-à-go-go-related gene (hERG) channels, which govern the outflow of potassium ions necessary for adequate cardiac repolarization between contractions. These channels are relatively easy to block, so a variety of disparate agents will occlude them, significantly prolonging the QT interval. This promotes the risk of ventricular arrhythmias, which, in turn, can lead to fatal ventricular fibrillation. QT prolonging drugs include several antihistamines such as astemizole and terfenadine, as well as antipsychotics, gastroprokinetics (cisapride), some tyrosine kinase inhibitors (dasatinib), and some fluoroquinolones. There are often marked differences in hERG receptor affinities between drugs of the same class, with some binding at therapeutic levels (pimozide and astemizole) while others show little or no binding (quetiapine and cetirizine) [155,156]. Many otherwise unexplained deaths are likely to have been linked with hERG blockade and CYP inhibitor combinations and this clinical area is not fully explored or understood. This is highlighted by the previously mentioned (section 1.4.4.2) surprising lack of difference in risk of TdP between old and new antipsychotics in TdP [121].

1.5.4.3 Rhabdomyolysis. This condition is characterized by the destruction of myocytes, releasing myoglobin into the blood. The first sign of this effect is dark colored urine, although the myoglobin then dissociates to form ferrihemate, which is toxic to the kidney. Although it can be caused by mechanical injury, there are many drugs, both licit and illicit that can cause the direct muscle injury that leads to rhabdomyolysis [157]. Statins are probably the best-known causes of this injury, although many other prescription drugs can cause it, such as paracetamol (acetaminophen) and antihistamines [158,159]. Drugs of abuse, such as ethanol, cocaine, and heroin, also cause the condition, but many other agents that induce sedation at higher plasma levels, such as antipsychotics, benzodiazepines, and antidepressants, increase the risk of rhabdomyolysis by reducing patient movement and exacerbating muscle damage [157]. Overall, CYP inhibitors that increase the plasma concentrations of all these agents may promote the appearance of rhabdomyolysis, which can lead to renal failure and death *in extremis*.

1.5.4.4 Sedation. Inhibition of the clearance of many centrally acting classes of drugs will promote their sedative effects and this is likely to be a problem with benzodiazepines, antipsychotics, antidepressants, antiepilepsy drugs and some antihistamines. This is of serious clinical significance if the patient becomes unresponsive and perhaps lives alone. The best-case scenario is that due to the patient's state, no further drugs will be ingested for a considerable period and the drugs are gradually cleared without permanent damage. The worst-case scenario might involve sufficient mental confusion to overdose.

1.5.4.5 Anticancer Agents. Several antineoplastic agents require some form of activation by CYPs to exert their clinical effect, and inhibition of biotransformational processes will hinder their efficacy or promote their accumulation, which can lead to toxicity [160]. Cyclophosphamide's CYP2B6-mediated conversion to an active acrolein derivative is hindered by CYP inhibitors such as ritonavir and efavirenz, which impair efficacy, while the taxols, docetaxel, and paclitaxel are cleared by CYP2C8 and inhibition magnifies their toxicity. In irinotecan therapy, inhibition of SN-38 glucuronidation can lead to severe neutropenia among other toxicities, although efficacy will be

enhanced, provided the patient can withstand the toxicity, as mentioned previously. In general, patients under treatment with anticancer agents can be highly susceptible to toxicity and efficacy problems in the presence of CYP inhibitors although fortunately, their clinical supervision is normally very close.

1.6 PATIENT FACTORS AFFECTING BIOTRANSFORMATION

1.6.1 The Elderly

After their possible polymorphic gene expression, probably the major influencing factor the patient brings to the process of drug therapeutics is their age. It is not completely clear in the literature at what point an individual is classed as “elderly,” although some studies suggest that those aged 70 plus should be thus considered [161]. Indeed, older individuals vary hugely in their general health, robustness, quality of nutrition and other personal habits that might impinge on drug clearance, such as drug or alcohol usage. It could be suggested that for the purposes of drug biotransformation, one does not suddenly become “elderly”; rather, all the processes mentioned earlier contribute to changes in drug clearance that are seen in older individuals and should be considered on an individual basis.

However, in all individuals, certain basic processes apply which are related to age, such as the gradual reduction in hepatic blood flow that can lead to a nearly 50% reduction by the patient’s late 60s compared with that of their early 30s [162,163]. Since many drugs are blood flow dependent in their clearance, such agents will show a proportionally similar reduction in clearance to the decline in blood flow. However, aside from blood flow decline, there is a reduction in the intrinsic clearance of several drugs (paracetamol, naproxen, and valproate) of between 20% and 60% [164]. This is linked to age-related changes in protein binding, as well as a reduction in the activity of some individual CYPs, such as CYP1A2, CYP2C9, and CYP2C19 [165,166], but not others such as CYP2D6 [167].

It might be expected that this mixed effect related to the effects of age on CYPs may be linked with changes in levels in basal hormone secretions; although a study in elderly men with growth hormone supplementation reported that CYP1A2 was induced, but other CYPs were unaffected (CYP3A4 and CYP2D6), while CYP2C19 was inhibited [168]. Processes such as CYP inhibition are likely to cause similar effects in the elderly. Alternatively, regarding induction, a study with St. John’s Wort demonstrated robust increases in CYP3A4 and CYP2E1 expression in a group of individuals with a mean age of 67 years [8]. Hence, it is likely that induction still presents a clinical problem in the elderly when adding inducers to existing regimes or adding to regimes that already contain inducers. Regarding the impact of age on basal expression of the various transporters, this may not be quantifiable due to the extraordinary variation in their expression between individuals [169], although given that induction is probably close to fully functional in an elderly individual’s CYP3A4, P-gp expression at least will probably also respond to induction, so the OATPs may follow suite. Regarding glucuronidation capacity, there is no evidence that this is diminished significantly in old age [170]; drugs that are cleared mainly by this pathway, such as AZT and lorazepam, are likely to show changes in clearance which are commensurate with the age-related blood flow reduction.

Overall, it is recommended that drug dosages should be considerably reduced (often up to half) for the elderly and careful note of concentration-dependent adverse reactions taken to ensure that they are not over medicated. While this applies in the case of the so-called fit elderly, the frail elderly, those with multiple pathologies, present a more considerable challenge. Not only are they likely to be the recipients of polypharmacy, but their general health and capability of their major organs such as renal, hepatic, and GI tract function, is likely to be suboptimal, leading to effects on absorption, distribution (plasma protein level changes), metabolism, and excretion.

1.6.2 Children and Neonates

The state of knowledge of drug clearance in neonates, generally those less than four weeks old, is relatively poor, partly because they are difficult to study for a number of reasons. It is generally accepted that it is highly questionable ethically to carry out clinical research on individuals who by definition cannot give informed consent and are extremely precious to their parents. They are also fragile, have low blood volume (a problem in repeated sampling) and less than stellar renal function, as well as relatively poor biotransforming capacity. It has been suggested that such research is better incorporated into an ongoing treatment programme, with such sedatives as midazolam at low doses [171]. The major CYP in fetal liver is CYP3A7, which has much lower capability than its adult equivalent CYP3A4, although it is more efficient at metabolizing some steroids; interestingly, CYP3A7 is not exclusively fetal, as around 10% of adults express it [172]. Generally, at birth, the neonate CYP hepatic content is less than a third of adults [173], although most CYP activity is on a par with adults within a year or so of birth [174]. Indeed, clearance of CYP3A4 substrates can be faster than adults within a couple of months of birth [175]. Regarding other oxidative pathways, neonates are born with high FMO-1 and low FMO-3 expression, but this reverses rapidly and FMO-3 becomes the dominant form that increases toward adulthood [176].

In contrast to CYPs and other oxidative pathways, UGT capacity is very low at birth and only increases very gradually [177]; indeed, the major UGT1A1, which processes bilirubin, is low in activity around the time of birth, which leads to many babies being born with a degree of mild jaundice, which is much more pronounced in UGT1A1 polymorphisms [178]. Adult levels of the UGTs appear from aged 6 months onward [5], although in general conjugative pathways take longer to mature than oxidative ones. Premature neonates have little drug-metabolizing capacity even in comparison with term neonates, so that they present a particularly difficult therapeutic management problem.

Overall, neonates and children are not miniature adults and have markedly different characteristics, based on dimensions, volumes, intrinsic enzyme capacity, renal performance, and protein binding; indeed, much remains to be discovered about their biotransformational capacity and its impact on drug efficacy and in particular, their vulnerability to drug toxicity [5,175].

1.6.3 Gender

There is considerable evidence in animal models that drug clearances vary between the sexes, partly related to possession or lack of possession of particular CYPs [179].

The effects of gender in humans is not so well characterized, but some CYPs do appear to have higher activities in males, such as CYP1A2, which leads to increased clearance in males with drugs such as clozapine; perhaps surprisingly, smoking is thought to be a larger factor in CYP1A2 activity than gender [180,181]. Overall, females have lower UGT and CYP2E1, higher CYP3A4 and CYP2B6, but the same CYP2C9 and CYP2D6 activities [5,182]. Interestingly, probably the most dangerous drug side-effect in terms of rapidly lethality, TdP, is more common in women due to estrogen effects and so more than 60% of the cases are female [5,182]. Women are also more at risk from other drug adverse reactions, such as rashes [183]. There are other factors that also govern female drug clearance, which include lower total body water, different basal metabolic rates, lower renal glomerular filtration rate, and generally lower body size and volume in comparison with men.

1.6.4 Pregnancy

It is sometimes assumed that only certain highly necessary classes of drug are prescribed during pregnancy, such as antiepileptic agents and antimalarials in appropriate areas. However, a study in Norway revealed that approximately a quarter of fathers and a little less than half of mothers had used prescription drugs in the three months before successful pregnancy and more than half of women continued to use prescription drugs during pregnancy [184]. These agents ranged from antidepressants to hormones, anti-infectives, anxiolytics, and antihistamines. This is highly significant, as aside from the teratogenic risks, drug clearance in pregnancy can also change due to marked distributional changes related to the process. There are steep reductions in the plasma concentrations of several drugs, such as the antiepileptics, as well as transmission of pharmacologically relevant doses to the fetus and neonate through the placenta and maternal milk, respectively [185]. There is little evidence of CYP activity of the placenta, apart from the induction of CYP1A1 in smokers [186]. Transporter activity, such as P-gp, in the placenta is predictably high, with fetal protection being a priority; however, there are marked differences in the transport of even drugs of the same class [187]. There is conflicting evidence that pregnancy affects CYP expression in animals [188,189]. In humans, CYP3A4 is induced by pregnancy, which is related to hormonal changes [190], leading to the suggestion that narrow therapeutic index drugs should be carefully monitored in pregnancy [6]. Overall, although sex differences are less clear in terms of CYPs in humans with respect to animal models, there are clearly enough differences in certain drug clearances to alert clinicians to the possibility that many pharmacokinetic as well as biotransformational factors may conspire to make women's drug therapy potentially more difficult to manage than men's.

1.6.5 Effects of Disease

Multiple pathologies may affect drug clearance, ranging from specific renal or hepatic organ malfunction, which may virtually arrest the clearance of many drugs and metabolites, to more subtle effects such as on the supply of protein for binding globulins or GIT problems that might impair absorption. There are several ongoing global conditions that affect CYP expression, such as diabetes, which induces CYP2E1 activity. This is shown in significantly increased clearance of chlorzoxazone in obese diabetics [191] compared with nondiabetics. However, the major focus in terms of disease on

biotransformational capability is usually in the liver. Any severe disruption of hepatic ultrastructure or metabolism either through disease (hepatitis or cancer) or abuse (cirrhosis) will strongly affect the ability of the organ to fulfill its main biochemical and physiological functions as well as affecting enzyme expression. Hepatitis viral infections, such as the C and B variants, can lead to cirrhosis and hepatocellular carcinoma and they affect liver cellular oxidative defense systems by reducing GSH maintenance, which increases hepatic oxidative stress [192]. Hepatitis C causes down-regulation in the expression of most CYPs, such as CYP2B6, CYP2C9, CYP2C19, CYP2E1, and CYP3A5, but it increases expression of others, such as CYP3A7 [193]. Several autoimmune conditions also lead to antibody formation that is directed at various CYPs, although the mechanisms at work are still not understood [194,195]. In general, CYP capability is reduced in hepatic disease and will affect drug clearance [196].

CYP2E1 expression is strongly linked with the oxidative stress that is associated with alcoholic liver disease [197], and the physical damage inflicted on the vasculature and ultrastructure of the organ is so severe that blood flow is severely restricted. The physical loss of functional hepatocytes, combined with the poor organ perfusion, is the major factor in the drastic loss of biotransformational capacity of the cirrhotic liver. In addition, CYP expression, such as CYP3A and CYP2E1, are both significantly reduced in the surviving hepatocytes [198].

1.6.6 Diet

Aside from the impact of agents such as the various fruit juices (discussed in Section 1.5.2.2), much of the research into the effects of diet on biotransformation is related to the etiology of cancer, such as the generation of toxic species that may damage DNA, through to dietary protective agents, which either inhibit or induce protective or potentially damaging pathways over many years. In terms of impact on drug clearance, unless a diet contains large amounts of cooked food rich in hydrocarbons (CYP1A2 induction) or steroids and phytosteroids (CYP3A family), there are few agents that can be ingested in sufficient quantity to alter drug clearance to a meaningful degree. There is evidence that cruciform vegetables contain potent CYP modulators such as sulforaphane and various indoles, which can clinically induce CYP1A2 capacity when eaten along with other crucifers [199,200]. Broccoli can also induce GSTs, acting to protect against reactive species generation [199]. Regarding the effects of dietary products on CYP induction, there are many agents that interact with PXR and other nuclear receptors; indeed, sulforaphane in broccoli is an antagonist of PXR, while other plant products are inducers [81]. Overall, the net effects on drug clearance of so many agents that are found in typical diets is highly individual and is probably very difficult to predict, given the variability inherent in human biotransformational enzyme expression [201].

1.7 DRUG METABOLISM AND DRUG DEVELOPMENT

1.7.1 Introduction

Drug metabolism is an integral aspect of drug development and has major implications in terms of not only efficacy and toxicity but also of patent protection

for pharmaceutical and biotechnology companies that spend hundreds of millions to develop and market a drug. For example in 1985, Seldane[®] (terfenadine) was the first nonsedating antihistamine to be brought to market by Hoechst Marion Roussel and was perceived in the UK to be safe enough for OTC use. The drug was withdrawn in 1998 in the United States and restricted to named patient only status in the United Kingdom because of the risk of cardiac arrhythmia caused by QT interval prolongation as a consequence of inhibition of CYP3A4-mediated metabolism of terfenadine. Ironically, fexofenadine (Allerga[®]), a carboxylated metabolite of terfenadine, marketed in 1998 as a backup to Seldane[®] by Hoechst Marion Roussel, did not exhibit the QT liability seen with Seldane[®]. In fact, terfenadine could be considered a prodrug of fexofenadine, and if the pharmaceutical company had spent more time/resources to characterize the metabolism of terfenadine and the pharmacology/toxicology of terfenadine metabolites, a safer analog could have been developed and marketed sooner.

1.7.2 The Drug Development Process

Drug development is both arduous and of long duration (10–12 years). It involves (i) the identification of a target, synthesis of possible drug candidates based on structures of known substrates and/or inhibitors of the target; (ii) high throughput *in vitro* screening for binding followed by *in vitro* and *in vivo* evaluation of efficacy in pre-clinical models; (iii) characterization of pharmacokinetics and disposition in rats, dogs, and/or monkeys to select the most promising compound; (iv) assessment of the compound's safety in animal toxicology studies to demonstrate that the drug candidate is reasonably safe to proceed with initial clinical trials in human volunteers (phase 1); (v) demonstration of proof of concept in the intended patient population and conduct DDI studies in phase 2; and (vi) the conduct of two large-scale pivotal clinical trials to demonstrate safety and efficacy to support the marketing application (phase 3). Given that 1 in 10,000 discovery compounds may make it as a drug, one has better odds in Las Vegas.

In silico and *in vitro* methods may be used in the early discovery phase as cost-effective means to “weed out” compounds with metabolic liabilities, such as the formation of reactive metabolites that may be responsible for idiosyncratic drug reactions, most notably hepatotoxicity or drug-induced liver injury (DILI). Yet, there are limitations with *in silico* methods as they rely on actual *in vivo* data. Drug candidates are typically screened *in vitro* for CYP450-mediated metabolic stability and potential CYP450 inhibition; induction studies are typically conducted later in preclinical development. *In vitro* data have been estimated to be predictive of the nature and level of circulating human metabolites from 41% [202] to >70% [203] of the time. Subsequent *in vivo* metabolism studies with unlabeled drug or radiolabeled drug, if available, can provide additional information. Various analytical methods, for example, LC-MS/MS, radiometric, and NMR, are used to analyze samples. During preclinical development, mass balance/metabolite identification studies in the rodent and nonrodent toxicology species are conducted with radiolabeled drug to determine the route(s) of elimination, mass balance, and metabolite identification. Radiolabeled drug is also used for the human mass balance/metabolite identification study, and this study is typically conducted during clinical development. These studies also provide information on clearance mechanisms, such as on renal and/or biliary excretion and metabolism.

1.7.3 Drug Metabolites and Drug Development

The consensus opinion entitled “Contemporary Issues in Toxicology, Drug Metabolites in Safety Testing” was published in 2002 [204]; this article became known as the Metabolites in Safety Testing (MIST) document. Its goal was to define reasonable, scientifically based approaches for the incorporation of metabolite data in the nonclinical safety evaluation of small molecules. In the nonclinical safety evaluation of drug candidates, determination of systemic exposure, that is, maximum observed drug concentration ($C_{\max}$) and area under the concentration–time curve (AUC), is critical for risk assessment and determination of margins of safety to support clinical trials. Unfortunately, metabolites are generally not considered in the risk assessment since their contribution to the overall toxicity profile observed is usually unknown. However, if the incidence and severity of adverse findings/toxicity do not correlate with the systemic exposure to parent drug, then it is likely that a metabolite may be responsible. Thus, the onus would be on the pharmaceutical company to determine the cause.

A major metabolite was defined as “one that accounts for 25% or more of the exposure to circulating drug-related material.” This threshold carries no regulatory authority or implications with respect to the need for safety assessment [205]. However, one must not lose sight that even minor metabolites can and often do cause toxicity.

The MIST document provides recommendations for the three major phases of drug development: (i) nonclinical (a.k.a, preclinical) development [i.e., candidate selection to Investigation of New Drug (IND) filing]; (ii) initial clinical safety, tolerability, and efficacy trials in human volunteers (phase 1 through 2b); and (iii) large-scale clinical trials for product registration (phase 3).

Even though there is no consensus from the members of the Pharmaceutical Research and Manufacturers Association (PhRMA) on the timing of metabolism studies in humans, it is recognized that attempts to identify differences in drug metabolism between animals used for nonclinical safety evaluation and humans be performed as early as possible. The Food and Drug Administration (FDA) and International Congress on Harmonisation (ICH) regulatory guidances do suggest that safety evaluation of metabolites be completed before the start of phase 3 trials. A *de minimis* approach for an IND filing would be to conduct comparative *in vitro* metabolite profiling studies using isolated hepatocytes, liver slices, or hepatic microsomal preparations from the toxicology species (e.g., rat, dog, and monkey) and humans to demonstrate that the toxicology species are being exposed qualitatively to the same metabolites seen in humans and to justify the selection of the nonrodent toxicology species (details on how these studies are conducted are addressed in other chapters of Volume 6). With regard to submission of Investigational New Medicinal Product Dossier (IMPD) in the European Union, it is recommended that *in vitro* studies be conducted before phase 1 to aid in determining whether volunteers of certain genotypes should be excluded and for extrapolation of nonclinical safety data to humans [206]. The use of radiolabeled drug (typically ^{14}C -labeled although ^3H can be used) is recommended to ensure quantitative recovery and facilitate identification of drug-derived constituents. Assurance that the metabolite profile in at least one of the toxicology species is qualitatively similar to that in humans is adequate for nonclinical safety assessment. Metabolite identification is not a prerequisite during preclinical development, but could aid the toxicologist in deciding whether to monitor metabolite(s) in the IND- or IMPD-enabling toxicology studies, especially if toxicity did not correlate with concentrations of unchanged drug in

the exploratory dose range-finding studies. Although it is rare that a metabolite formed in humans is not found in the toxicology species, in those cases where a unique human metabolite is formed or a human metabolite is produced disproportionately (i.e., abundance) in the toxicology species, independent nonclinical safety studies with the human metabolite may be warranted.

The MIST document recommends that *in vivo* metabolite identification be conducted in the toxicology species and in humans sometime in phase 1 through 2b. An *in vivo* metabolism study in which the drug is administered both orally and intravenously provides information on the degree of first-pass metabolism by the GI tract and/or liver. Synthesis of prevalent metabolites is performed for metabolite confirmation and subsequent testing for efficacy in pharmacology models. Metabolism information aids the pharmacokineticist in the design of subsequent studies such as CYP450 reaction phenotyping, *in vitro* drug induction/inhibition, *in vitro* transporter interaction, and clinical DDI studies. Information gained from metabolism, CYP450 reaction phenotyping, *in vitro* drug induction/inhibition, and *in vitro* transporter interaction studies helps assess the DDI potential of a development candidate and whether clinical DDI studies are warranted. Furthermore, additional investigations to assess the contribution of metabolites in the overall toxicity profile of a drug candidate may be warranted in those cases where the therapeutic index is narrow. The MIST document emphasizes that all major human circulating metabolites should be present in at least one of the animal species used in the reproductive toxicology studies. Carcinogenicity studies on administered major metabolite are not recommended or routinely conducted; however, the FDA reserves the right to request such studies when appropriate.

The FDA guidance entitled “Safety Testing of Drug Metabolites” was issued by the Center for Drug Evaluation and Safety (CDER) in February 2008. “The safety of drug metabolites may need to be determined in nonclinical studies because these metabolites are either identified only in humans or are present at disproportionately higher levels in humans than in any of the animal species used during standard nonclinical toxicology testing” [207]. The guidance further states that human metabolites that may pose a safety concern are those found circulating at >10% of parent drug systemic at steady state (in contrast to 25% cited in the MIST document). The FDA recommendation is, however, consistent with ICH Harmonised Tripartite Guideline M3(R2) [208] in terms of the 10% level but ICH M3(R2) does not specify steady state. The confounding factor with radiolabeled mass balance/metabolite identification studies is that a single dose (i.e., nonsteady state) is used. However, an estimate of exposure at steady state could be derived from an accumulation ratio calculated using the elimination rate constant and anticipated dosing interval.

Two approaches for assessing metabolite safety are outlined in the FDA guidance: (i) identification of a toxicology species that forms the metabolite at exposures comparable to or greater than human exposure and evaluation of toxicity of the drug candidate in that species or (ii) if a toxicology species that forms the metabolite cannot be identified, the metabolite should be administered to animals at multiples of human exposure, if possible, for evaluation of toxicity by the intended clinical route. One-to-one coverage of metabolite in one toxicology species would generally be sufficient to qualify the metabolite (this assumes that metabolite exposure in the toxicology species was comparable to human exposure of the metabolite at the maximum recommended therapeutic dose). The duration of general toxicity studies with direct administration

of metabolite should follow ICH M3(R2) [208] and, as a minimum, cover the duration of clinical administration or, as a disproportionate (i.e., abundance) metabolite, its genotoxic potential should be assessed *in vitro* in a mutagenicity and a clastogenicity assay. Embryo-fetal development toxicity studies should also be performed with the metabolite. It is possible that the FDA may accept such a study in only one species that forms the metabolite, while other reproductive studies may be requested by the FDA, depending on the findings in the general toxicity and embryo-fetal development studies. If a drug is administered continuously for at least six months or is used for chronic intermittent treatment and the carcinogenic potential of the metabolite cannot be adequately assessed in carcinogenicity studies with the parent drug, independent carcinogenicity studies should be conducted with the metabolite. With regard to any proposed carcinogenicity studies, the Carcinogenicity Assessment Committee at the FDA should be consulted before study initiation.

Systemic concentrations of metabolites are dictated by the rate and extent of biotransformation of parent, extent of tissue distribution and degree of binding to plasma and tissues, and metabolite clearance rates. All three factors can differ across species, but biotransformation of parent and metabolite clearance are likely to differ the most between animals and humans due to differences in drug-metabolizing enzymes, especially CYP450. [209]. DDIs represent an important source of variability in pharmacokinetics that can affect drug response, in terms of efficacy as well as toxicity. The recommended timing of metabolism and drug interaction studies in FDA guidance is essentially the same in the European Medicines Agency (EMA) Guidelines on the Investigation of Drug Interactions (draft); however, the EMA draft guideline emphasizes that “the potential effects of metabolites on the pharmacokinetics of other drug as well as effects of other medicinal products on the exposure of active metabolites should always be considered” [206].

There have been several articles published on MIST. Some publications have advocated that rather than using a percentage-based approach as recommended in the MIST document, absolute abundance (amount or concentration), the nature of the toxicity mechanism (reversible vs covalent binding), and the biological matrix in which the metabolite was observed (circulatory vs excretory) be used when comparing metabolites across species and making decisions regarding whether to assess the contributions of metabolites to toxicity [209,210]. A fourth tenet, duration of exposure, has recently been added to that decision tree [211,212]. The proposed “new MIST” strategy of considering metabolite structure, amount, biofluid, potential mechanism of toxicity, and duration of exposure is insightful, but the guiding principles proposed may be of limited utility given the number of drugs examined retrospectively in each toxicity class.

The results of independent toxicity testing of an administered metabolite may be misleading and fail to characterize the contribution of metabolite to the overall toxicity of the drug candidate due to differences in the pharmacokinetics and disposition of administered metabolite compared to that formed *in situ* following administration of parent. The discrepancies are not only due to differences between the drug candidate and metabolite in physicochemical properties and interactions with transporters and/or drug-metabolizing enzymes but also by physiological factors such as tissue selective distribution and species differences in transporters and/or metabolizing enzymes [213]. These factors may be mitigated/compensated for, in part, if higher exposure to metabolite can be achieved (e.g., by increasing dose or dose frequency) in nonclinical toxicity studies with the metabolite alone.

1.7.4 Drug Development and Drug Interactions

In developing a drug, the goal is to select a candidate that has a favorable pharmacokinetic profile that entails good absorption/bioavailability, linear pharmacokinetics, an elimination half-life which would support the intended clinical dosing regimen, not extensively metabolised and does not possess pharmacokinetic DDI liabilities. Sometimes, trade-offs are made with regard to the desired pharmacokinetic properties for the sake of efficacy or the lack of available or effective medications for a serious or life-threatening disease state. Refractory epilepsy is a good example. Typically, patients with refractory epilepsy are on multiple drugs. The first generation of AEDs, such as phenobarbital, phenytoin, valproic acid, and carbamazepine, are still commonly used today as baseline therapy and are either CYP450 inducers or inhibitors. As pharmaceutical companies continue to develop newer AEDs for add-on therapy, the goal is to reduce or eliminate DDI potential. Eslicarbazepine acetate, felbamate, lamotrigine, oxcarbazepine, tiagabine, topiramate, and zonisamide are susceptible to inhibition and induction of their own metabolism [214]. Gabapentin [215], pregabalin [216], and vigabatrin [217] are excreted essentially unchanged in the urine and are not CYP450 inducers or inhibitors. As stated by Bialer and White [218], a new AED can be successful if at least one of the following criteria are met: greater efficacy in refractory epilepsy than AEDs in current use, the ability to prevent or delay the onset of epilepsy and/or potential for disease modification; broad use in other nonepileptic CNS disorders, fewer side effects and/or better tolerability than currently used AEDs, and improved ease of use (rapid titration, linear pharmacokinetics, a lack of drug interaction, and once- or twice-daily dosing).

1.7.5 Drug Development and Pharmacogenetics

The CYP450 isozymes (specifically, CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4/5) are the principal oxidative drug-metabolizing enzymes. CYP2C9, CYP2C19, and CYP2D6 are expressed polymorphically and enzymatic activity differs among ethnic groups such that individuals can be categorized as PMs or EMs and dose adjustment would be warranted to avoid toxicity or lack of efficacy.

For example, metabolism of clopidogrel, a prodrug, via CYP2C19 is essential in the management of patients with acute coronary syndrome (ACS). Biotransformation of clopidogrel by the CYP2C19*2 allele, which is present in 30% of some populations, results in reduced production of the active metabolite and is associated with increased risk of adverse events, such as stent thrombosis [219,220]. Development of prasugrel was a major advancement in that biotransformation of prasugrel to its active metabolite was primarily by CYP3A and CYP2B6 [221]. In the case of CYP2D6, Asians, Pacific Islanders, Africans, and African-Americans have a higher percentage (~40% to 50%) of reduced or nonfunctional CYP2D6 relative to Caucasians (26%) [222]. Hence, pharmaceutical companies have avoided developing drugs that are predominantly (>90%) metabolized by CYP2C9, CYP2C19, or CYP2D6.

Since CYP3A4 is responsible for the metabolism of ~60% of marketed drugs, drug candidates that are exclusively metabolized by CYP3A4 or are potent inhibitors of CYP3A4 pose a serious liability for pharmacokinetic drug interactions and would be subject to labeling restrictions with regard to coadministration with other drugs.

The antidepressant nefazodone (Serzone®) is an excellent example (mentioned in Section 1.5.2.3), since the drug is a substrate and inhibitor of CYP3A4 as well as a hepatotoxin due to the formation of a reactive metabolite. The Serzone® product label lists several DDIs, including triazolam, alprazolam, buspirone, atorvastatin, simvastatin, terfenadine, astemizole, cisapride, or pimozide. On the basis of the proposed structure of the glutathione conjugate with nefazodone, a bioactivation sequence involving aromatic *ortho*- or *para*-hydroxylation on the quinolinone followed by oxidation to a quinone-imine was proposed [223]. Serzone® was not surprisingly voluntarily withdrawn from the US market in 2004.

In summary, there is no straightforward or standardized approach to deal with metabolites in safety studies. The number and type of nonclinical studies for drug metabolites could be abbreviated in the case of serious illness (e.g., amyotrophic lateral sclerosis, stroke, and human immunodeficiency virus) or may not be necessary (e.g., cancer) [207]. Using a weight of evidence approach to demonstrate a minimal safety concern, a waiver may be requested from the Agency. In both the MIST document [204,224] and the FDA guidance on Safety Testing of Drug Metabolites, a case-by-case approach to metabolite safety testing is advocated, given the complexity faced in the development of a drug candidate. Although it recognized that there are differences in drug-metabolizing enzymes between animals and humans, the question of how to extrapolate drug metabolism and associated toxicities in animal species to humans challenges the pharmaceutical industry. Finally, metabolism is an important factor that must be addressed during both preclinical and clinical development. Biotransformation can result in the formation of reactive metabolites, reduced or no efficacy, formation of pharmacologically active metabolites, and inducers/inhibitors of major drug-metabolizing enzymes (e.g., CYP450 and UDPGA-transferases).

1.8 CONCLUSIONS

It is to be hoped that this introductory chapter has given the reader some inkling of the sheer scale of the challenges facing the design, development, and successful deployment of clinically effective drugs in human populations. The multiplicity of biotransformational processes that affect drug efficacy and toxicity, ranging from transporters, CYPs, UGTs, SULTs, and their control systems presents huge challenges in the everyday use of potentially life-enhancing medicines. Continued research into human age, gender, genetic, and phenotypic variation, which informs so much of drug impact on patients, will in time improve drug targeting, maximizing efficacy and minimizing toxicity. It is also vital that not only is such research carried out ethically and scientifically, it must also be disseminated to prescribing healthcare professionals the world over to translate clinical research advances into real and sustained gains in patient health during drug therapy.

2.1 INTRODUCTION

The CYP450 (P450) is a collective name for a very large group of enzymes found in all domains of life and are responsible for the metabolism of a vast array of xenobiotic chemicals, including drugs, carcinogens, pesticides, pollutants, and food toxicants as well as endogenous compounds, such as steroids, prostaglandins, and bile acids [1,2]. The origin of the cytochrome P450 name, first coined in 1962, was from the fact that these enzymes are cellular (cyto) colored (chrome) proteins, which contain heme pigments (P) that absorb light at a wavelength of 450 nm when exposed to carbon monoxide [3,4]. P450 enzymes are predominantly expressed in the liver as well as in extrahepatic tissues such as lungs, kidneys, intestine, brain, and skin. Since their discovery at the end of 1950, P450 research has grown and the multiplicity and complexity of the P450 system has been evident for more than five decades [5]. Over 11,500 members or distinct P450s genes are currently known that are present in the majority of species from all biological kingdoms [6,7].

The P450 enzymes catalyze oxidative as well as some reductive (phase I) reactions. These reactions introduce or unmask a functional group (e.g., –OH, –CO₂H, –NH₂, or –SH) within a molecule to enhance its hydrophilicity. It can occur through direct introduction of the functional group (e.g., aromatic and aliphatic hydroxylation) or by

modifying existing functionalities (e.g., oxidative hydrolysis of the esters and amides, oxidative N-, O-, and S-dealkylation, and reduction of aldehydes and ketones) [8]. As a result, more hydrophilic (water soluble) and polar entities are formed, which are eliminated from the body. In general, metabolism leads to compounds that are generally pharmacologically inactive and relatively nontoxic. However, metabolic biotransformation of drugs at times can lead to the formation of metabolites with pharmacological activity [9] or toxicity [10].

P450 enzymes have long been of interest in the metabolism of pharmaceuticals and other xenobiotics, since these enzymes are responsible for the elimination of majority of the marketed drugs. These reactions account for ~95% of the drug metabolism. In addition, there are a number of endogenous and exogenous factors, such as genetic variation, age differences, hormone levels, diet, and exposure to a variety of drugs, that can influence the expression and catalytic properties of P450 enzymes. Tremendous progress has been made in the last six decades in the characterization, expression, function, and regulation of P450 enzymes in animals and humans [2,11]. In this chapter, we summarize the most recent advances in our knowledge and application of P450 enzymes in drug discovery and development with particular emphasis on their involvement in the metabolism of drugs. In addition, we describe the species and ethnic variation in the expression of P450 enzymes and the tools used to extrapolate metabolism and toxicity in animals to humans.

2.2 NOMENCLATURE AND CLASSIFICATION OF HUMAN CYP ENZYMES

P450 enzymes are categorized into families, subfamilies, and specific enzymes according to their amino acid sequence similarity. P450s that share at least 40% sequence identity are placed within the same family, designated by an Arabic numeral, while those with greater than 55% homology are placed in the same subfamily, designated by a capital letter and those with 97% homology represent individual enzymes, designated again by a number. Individual alleles are designated by appending a star and a number (human cytochrome P450 allele nomenclature committee, <http://drnelson.utmem.edu/Cytochrome450.html>) (Fig. 2.1).

2.3 CATALYTIC ACTIVITY OF CYP ENZYMES

The P450 enzymes are referred to as *hydroxylases*, *monooxygenases*, or *mixed function oxidases* and possess three known types of activities. P450s, acting as hydroxylases, activate molecular oxygen and insert one atom of molecular oxygen into the substrate (S or X) while reducing the other atom of oxygen to water (Eqs. 2.1 and 2.2). As a result, the xenobiotics can undergo hydroxylation, epoxidation, heteroatom (N-, S-) oxygenation, heteroatom (N-, S-, O-) dealkylation, ester cleavage, isomerization, dehydrogenation, and oxidative dehalogenation.

Figure 2.1 Nomenclature of CYP450 enzymes.

The oxidase activity of P450s involves one electron transfer from reduced P450 to molecular oxygen with the formation of superoxide anion radical and H_2O_2 (Eq. 2.3a,b).

The reductase activity of P450s involves direct electron transfer to reducible substrates such as quinones and proceeds readily under anaerobic conditions.

The catalytic cycle of P450 oxidation is a complex multistep processes as follows:

1. P450 enzyme (Fe^{3+}) first binds to a substrate XH to form $\text{Fe}^{3+}\text{-XH}$. This results in lowering the redox potential, which makes the transfer of an electron favorable from its redox partner, NADH or NADPH. This is accompanied by a change in the spin state of the haem iron at the active site.
2. The next step in the cycle is the first reduction of the $\text{Fe}^{3+}\text{-XH}$ to $\text{Fe}^{2+}\text{-XH}$ by an electron transferred from NAD(P)H via an electron-transfer chain.
3. In the third step, an O_2 molecule binds rapidly to the $\text{Fe}^{2+}\text{-XH}$ to form $\text{Fe}^{2+}\text{-O}_2^{\cdot-}\text{-XH}$, which then undergoes a slow conversion to a more stable complex $\text{Fe}^{3+}\text{-O}_2^{\cdot-}\text{-XH}$.
4. The next step in the cycle is a second reduction of $\text{Fe}^{3+}\text{-O}_2^{\cdot-}\text{-XH}$ to $\text{Fe}^{3+}\text{-O}_2^{2-}\text{-XH}$ via the electron donors either NADPH or cytochrome *b5*. This has been determined to be the rate-determining step of the reaction.

5. The $\text{Fe}^{3+}\text{-O}_2^{2-}\text{-XH}$ reacts with two protons from the surrounding solvent, breaking the O–O bond, forming water and leaving an $(\text{Fe-O})^{3+}\text{-XH}$ complex.
6. The Fe-ligated O atom is transferred to the substrate forming a hydroxylated form of the substrate ($\text{Fe}^{3+}\text{-XOH}$).
7. The last step involves the release of product from the active site of the enzyme, which returns to its initial state.

2.4 COMMON CYP-MEDIATED BIOTRANSFORMATION REACTIONS

P450 catalyzed reactions can be classified into four broad categories: (i) hydroxylation reactions where a hydroxyl group replaces a hydrogen atom; (ii) epoxidation reactions where an oxygen atom is introduced into carbon–carbon double or triple bond; (iii) heteroatom oxidation where an oxygen atom is added to a nitrogen or sulfur, (iv) dehydrogenation reactions where two hydrogen atoms are replaced by a double bond [12].

2.4.1 Hydroxylation Reaction

Hydroxylation of an aliphatic carbon or an aromatic ring is one of the most common drug metabolism reactions. The other common biotransformation reaction is the hydroxylation at the α carbon to a hetero atom, which resulted in oxidative cleavage of the molecule.

2.4.1.1 Aliphatic Hydroxylation. For aliphatic hydroxylation, one proposed mechanism is an abstraction of a hydrogen atom by $(\text{Fe-O})^{3+}$ to form a radical intermediate that reacts with the oxygen on the P450 ($\text{Fe-OH})^{3+}$ to yield the alcohol and $(\text{Fe})^{3+}$ (Fig. 2.2).

Drug molecules possess many alkane carbons with abstractable hydrogen atoms and therefore, hydroxylation can possibly occur at any one site that can result in more than one hydroxylated product, as shown for ezlopitant (Fig. 2.3) [13]. However, a product forms preferentially from the most stable radical (resonance stabilized such as benzylic or allylic).

2.4.1.2 Aromatic Hydroxylation. The aromatic hydroxylation occurs by epoxidation of the aromatic ring to form of an arene oxide, which undergoes a 1,2

Figure 2.2 Proposed mechanism of aliphatic hydroxylation.

Figure 2.3 Isomeric hydroxylated human metabolites of ezlopitant.

hydrogen shift (NIH shift) and subsequent tautomerization to yield a stable phenol product.

As a result, CYP-mediated aromatic hydroxylation often results in the formation of isomeric hydroxylated products. Owing to resonance stabilization, for monosubstituted phenyl groups, the rate of formation of hydroxylated metabolites is usually: para > ortho > meta.

Oxidation of lasofoxifene is primarily catalyzed by CYP3A4/3A5 and CYP2D6 and leads to formation of isomeric phenols (Fig. 2.4) [14].

2.4.1.3 Hydroxylation at α Carbon to a Hetero Atom (Oxidative O- or N-Dealkylation). Hydroxylation at the α carbon to a hetero atom (O, S, and N) yields an unstable intermediate that decomposes to an aldehyde, and alcohol, thiol, or amine, respectively.

N- and O (S)-dealkylation is a common reaction involving drugs containing a secondary or tertiary amine, alkoxy group, or an alkyl-substituted thiol. For example, ziprasidone, an antipsychotic drug, is metabolized to an aldehyde and benzisothiazole by CYP 3A (Fig. 2.5) [15].

Figure 2.4 Monohydroxylated metabolites of lasofoxifene in humans.

Figure 2.5 N-Dealkylation of ziprasidone.

Figure 2.6 Oxidative amide hydrolysis of torcetrapib.

2.4.1.4 Oxidative Ester/Amide Cleavage. Oxidative ester and amide hydrolysis is another common reaction that involves a multistep process: hydroxylation, dissociation of an unstable intermediate, and decarboxylation.

Hydrolysis can also be mediated by non-CYP enzymes, such as hydrolases, through nonoxidative processes. The distinction between the oxidative reaction and nonoxidative hydrolysis is demonstrated by the dependence on NADPH-P450 reductase and NADPH. CYP3A-mediated oxidative hydrolysis of an amide was a major metabolic pathway for the torcetrapib (Fig. 2.6) [16].

2.4.2 Epoxidation

Compounds containing double bonds, triple bonds, and aromatic groups can be subjected to CYP-mediated epoxidation as shown below.

Epoxidation results in the formation of unstable products, which hydrolyze by EHs to form diols or react with nucleophilic groups in macromolecules to initiate toxicological effects. [17]. Epoxides can also be further biotransformed to stable metabolites, as in the case of formation of a carboxylic acid metabolite of erlotinib (Fig. 2.7) [18].

2.4.3 Heteroatom Oxidation

Secondary, tertiary, and aromatic amines are subjected to N-oxidation, which is mediated by a large spectrum of enzymes including CYPs and FMOs.

Figure 2.7 Major metabolic pathway of erlotinib in humans.

Figure 2.8 CYP3A-catalyzed S-oxidation of ziprasidone.

This reaction can result in formation of either the *N*-oxides or the hydroxylamines.

Similarly, thiols are metabolized by S-oxidation to sulfoxide and sulfone as shown for ziprasidone (Fig. 2.8) [15].

2.4.4 Dehydrogenation Reactions

Desaturation often accompanies C-hydroxylation, but there are several examples where the alkene metabolites are known not to be formed from dehydration of the initial alcohol metabolites. Dehydrogenation reactions occur by abstraction of a hydrogen atom by the $(\text{Fe-O})^{3+}$ species to form a carbon-centered radical. Abstraction of another hydrogen atom results in double bond formation as shown below.

We identified an alkene metabolite of ezlopitant, a highly potent and selective NK1 receptor antagonist in humans [13]. It is the result of the desaturation of an isopropyl

Figure 2.9 CYP3A-catalyzed dehydrogenation of ezlopitant.

group and not from dehydration of the alcohol metabolite. Further, *in vitro* studies using human hepatic microsomes and recombinant human P450 isoforms suggested that the alkene metabolite is formed predominantly by cytochrome P450 CYP3A4/3A5 (Fig. 2.9).

2.5 SPECIES VARIATION IN THE EXPRESSION AND ACTIVITY OF CYP ENZYMES

Animal species at the preclinical stage are often used to predict the pharmacological and toxicological properties, as well as the metabolism of new chemical entities in humans. However, important differences in enzyme expression, selectivity, and catalytic activities of P450s between humans and animals often exist which can limit the direct extrapolation to humans from preclinical species. Therefore, some understanding of the similarities and differences of P450s among species is critical to the identification of relevant drug metabolism and predictive toxicology species. Humans possess 57 CYP genes, mice have 102 genes, while dogs and rats have 54 genes (for details: <http://drnelson.utmem.edu/cytochromeP450.html>). There are relatively small differences in the primary amino acid sequences of P450s across species, although, these small differences can give rise to profound changes in substrate specificity and catalytic activity.

This section focuses on human P450s involved in drug metabolism and their comparison with related P450s in preclinical species (mouse, rat, dog, and monkey).

2.5.1 Human CYP450 Enzymes

The functions of the 57 known human CYP enzymes are summarized into 3 main categories [19]. It has recently been suggested that 15 of the enzymes are mainly involved in the metabolism of clinically used drugs; 27 enzymes are responsible for the metabolism of endogenous compounds such as bile acids, eicosanoids, fatty acids, vitamins, and steroids; and the function of remaining 15 enzymes is unknown. Recent update from Drug Interaction Database of University of Washington (<http://www.druginteractioninfo.org/Query/EnzymeQueries>) indicated that the P450 enzymes from subfamilies CYP1A, CYP2A, CYP2B, CYP2C, CYP2D, CYP2E, and CYP3A are responsible for hepatic metabolism of majority of the marketed drugs. The individual P450 enzymes in these subfamilies involved in the metabolism of drugs are summarized in Table 2.1.

TABLE 2.1 Major P450 Isoforms in Human, Mouse, Rat, Dog, and Monkey

CYP	Human	Mouse	Rat	Dog	Monkey	Typical Substrate and Activity
1A	1A1, 1A2	1a1, 1b2	1A1, 1A2	1A1, 1A2	1A1, 1A2	Phenacetin O-deethylation, caffeine 3-N-demethylation, theophylline-N-demethylation
1B	1B1	1b1	1B1	1B1	1B1	Hydroxylation of 17 β -estradiol benzopyrene
2A	2A6, 2A7, 2A13	2a4, 2a5, 2a12, 2a22	2A1, 2A2, 2A3	2A13, 2A25	2A23, 2A24, 2A26	Coumarin 7-hydroxylation
2B	2B6, 2B7	2b9, 2b10, 2b13, 2b19	2B1, 2B2, 2B3, 2B12, 2B15, 2B31	2B11	2B17	Efavirenz 8-hydroxylation, bupropion hydroxylation
2C	2C8, 2C9, 2C18, 2C19	2c29, 2c37, 2c38, 2c39, 2c40, 2c44, 2c50, 2c54, 2c55	2C6, 2C7, 2C11, 2C12, 2C13, 2C22, 2C23	2C21, 2C41	2C20 (2C8), 2C43 (2C9)	Paclitaxel 6 α -hydroxylation (2C8), diclofenac 4'-hydroxylation (2C9), tolbutamide methyl-hydroxylation (2C9), S-warfarin 7-hydroxylation (2C9), S-mephenytoin 4'-hydroxylation (2C19)
2D	2D6, 2D7, 2D8	2d9, 2d10, 2d11, 2d12, 2d13, 2d22, 2d26, 2d34, 2d40	2D1, 2D2, 2D3, 2D4, 2D5, 2D18	2D15	2D17, 2D19, 2D29, 2D30, 2D42	Bufuralol 1'-hydroxylation, dextromethorphan O-demethylation
2E	2E1	2e1	2E1	2E1	2E1	Chlorzoxazone 6-hydroxylation
3A	3A4, 3A5, 3A7, 3A43	3a11, 3a13, 3a16, 3a25, 3a41, 3a44	3A1 (3A23), 3A2, 3A9, 3A18, 3A62	3A12, 3A26	3A8 (3A4), 3A5, 3A7, 3A43	Midazolam 1-hydroxylation, testosterone 6 β -hydroxylation
4A	4A11, 4A22	4a10, 4a12, 4a14	4A1, 4A2, 4A3, 4A8	4A36, 4A37, 4A38, 4A39	4A11	Lauric acid 12-hydroxylation

Figure 2.10 Relative abundance of major human (a), rat (b), dog (c), and monkey (d) hepatic P450 isoforms involved in drug metabolism. (See color insert.)

Figure 2.11 Percentage of drugs metabolized by each CYP isoform.

Each P450 enzyme is not evenly expressed in the human liver; indeed, CYP1A1 and CYP1B1 are expressed constitutively at extremely low levels. The relative abundance of major P450 enzymes is listed in Fig. 2.10a. Abundance of an individual P450 does not accurately reflect its contribution in drug metabolism. While CYP2D6 represents only ~5% of CYP enzymes in the liver, but it metabolizes ~12% of the marketed drugs (Fig. 2.11). CYP3A, the most abundant enzyme, constitutes 28% of the human liver and is responsible for metabolism of ~38% of drugs [20]. Recently, the percentage of metabolized drugs for CYP2C has been considerably increased to 28% (Fig. 2.11). The clinically relevant inhibitors and inducers of major human P450 enzymes are listed in Table 2.2.

TABLE 2.2 Examples of Clinically Relevant Inhibitors and Inducers of Major Human CYP450 Enzymes

1A2	2B6	2C19	2C9	2D6	3A
<i>Inhibitors</i>					
Acyclovir	Clopidogrel	Cimetidine	Amiodarone	Amiodarone	Amiodarone

2.5.1.1 CYP1A Family. In this P450 subfamily, all mammalian species possess two conservative and inducible members, namely, CYP1A1 and CYP1A2. CYP1A1 is present predominantly in the extrahepatic tissues such as lung, small intestine, placenta, and kidney, and at a very low level in the liver. CYP1A1 mainly catalyzes activation of polycyclic aromatic hydrocarbons (PAHs), aromatic amines, and heterocyclic amines. For example, the potent carcinogen, benzopyrene is metabolized to an epoxide almost exclusively by CYP1A1. The high variability of CYP1A1 in humans could arise from smoking and diet with high aromatic hydrocarbons such as charcoal-broiled meat and cruciferous vegetables.

In contrast to CYP1A1, CYP1A2 is mainly expressed in the human liver and catalyzes the oxidation of mutagenic and carcinogenic heterocyclic amines. A number of popular drugs, including tacrine, ropinirole, acetaminophen, riluzole, theophylline and caffeine, are metabolized by CYP1A2. CYP1A2 catalyzes the O-dealkylation of 7-methoxyresorufin and 7-ethoxyresorufin [21]. CYP1A2 is also involved in the demethylation of caffeine, which is used as an *in vivo* probe (blood, urine, or saliva) for CYP1A2 activity. CYP1A1 and CYP1A2 both are transcriptionally regulated by aryl hydrocarbon receptor (AhR) [22]. They are inducible not only by food and smoke but also from different drugs such as omeprazole, lansprazole, β -naphthoflavone, and 3-methylcholanthrene [8]. Several studies indicate slightly higher CYP1A2 activity in males compared to females [23]. Its level varies enormously from one individual to another but genetic defects are rare.

There are several clinical relevant inhibitors such as acyclovir, cimetidine, ciprofloxacin, famotidine, fluvoxamine, furafylline, mexilitene, α -naphthoflavone, norfloxacin, propafenone, verapamil, and zileuton for CYP1A enzymes. Coadministration of enoxacin (an inhibitor of CYP1A2) decreases the clearance of warfarin (a CYP1A2 substrate) [24]. Ketoconazole, a well-known 3A4 inhibitor, is also known to inhibit CYP1A1 in humans [25].

2.5.1.2 CYP1B Subfamily. In humans, only one CYP1B1 gene is identified and sequenced by Sutter *et al.* [26]. It is widely distributed and expressed in heart, brain, placenta, lung, liver, kidney and prostate, but in disease conditions, expression levels in tumor cells are much higher compared with normal tissues [27,28]. It is a key enzyme for the estrogen homeostasis, particularly, for the metabolism of 17 β -estradiol, and expressed at high levels in estrogen-related tissues such as mammary, uterus, and ovary [29]. CYP1B1 is also known to participate in the metabolic activation of a

number of procarcinogens, including PAHs, PAH-dihydrodiols, and aromatic amines [30,31]. AhR and AhR nuclear translocator regulate the induction of CYP1B1.

2.5.1.3 CYP2A Subfamily. The CYP2A subfamily includes three members in humans, CYP2A6, 2A7, and 2A13. CYP2A6 constitutes ~4% of the total hepatic P450 in human liver, whereas CYP2A7 and 2A13 are expressed at much lower levels [32]. Both CYP2A6 and 2A13 are active toward many carcinogens and other toxicants. CYP2A6 is mainly involved in O-deethylation of 7-ethoxycoumarin; hydroxylation of coumarin; and oxidation of nicotine, cyclophosphamide, ifosfamide, fadrozole, and aflatoxin [33,34]. Currently, there are nine marketed drugs that are substrates for CYP2A6. Diethyldithiocarbamate [35], methoxsalen, pilocarpine, tranylcypromine, and tryptamine are known to inhibit CYP2A6 in humans. CYP2A6 expression and activity are induced by phenobarbital, rifampicin, dexamethasone, nicotine, and pyrazole. CYP2A13 is predominantly expressed in the human respiratory tract and plays a major role in the activation of aflatoxin B1 [36] as well as in nicotine metabolism [37].

2.5.1.4 CYP2B Subfamily. CYP2B family consists of two members, CYP2B6 and CYP2B7. CYP2B6 is expressed mainly in the liver, whereas CYP2B7 is found in the lung tissue [38]. CYP2B6 is involved in the metabolism of ~5% of the marketed drugs, including bupropion, efavirenz, S-mephenytoin, methoxyflurane, and propofol. CYP2B6 accounts for <1% of total hepatic CYP content in humans. CYP2B6 polymorphism and inductions are known to cause significant interindividual differences in hepatic CYP2B6 expression [39], leading to significant changes in the degree of exposure to a variety of drugs. Several agents, such as ticlopidine, sertraline, clopidogrel, phenylethylpiperidine, 3-isoproprenyl-3-methyl diamantine, and 2-isoproprenyl-2-methyl diamantine, are known to inhibit CYP2B6 in humans. This CYP is inducible by rifampin, phenytoin, phenobarbital, carbamazepine, felbamate, and the herbal preparation St. John's Wort (Table 2.2). Rifampin is known to coinduce CYP2B6 with 3A4 and several CYP2C enzymes by activating constitutive androstane receptor (CAR) and pregnane X receptor (PXR). Recent studies have reported that females express significantly higher amounts of CYP2B6 than males.

2.5.1.5 CYP2C Subfamily. CYP2C subfamily includes four members, CYP2C8, CYP2C9, CYP2C18 and CYP2C19, and all together involved in the metabolism of about 28% of the marketed drugs. They are expressed mainly in the liver and are present at low levels in the small intestine [40]. CYP2C subfamily accounts for 18–25% of the total CYP content in the human liver [41]. CYP2C8 and CYP2C9 are the major enzymes, accounting for ~35% and ~60% of the total human CYP2C, while CYP2C18 and CYP2C19 account only ~4% and 1%, respectively. CYP2C8 is involved in the metabolism of several drugs such as anticancer drugs paclitaxel (Taxol®), amodiaquine, torsemide, and repaglinide and endogenous substrates including retinol and retinoic acid, arachidonic acid (AA) [42]. Specifically, repaglinide was recommended to be a CYP2C8 substrate by the United States Food and Drugs Administration (FDA). Exposure of repaglinide increases from 5.5- to 15-fold in the presence of a CYP2C8 inhibitor, gemfibrozil. CYP2C8 can also metabolize several glucuronide conjugates and this characteristic plays a crucial role in the mechanism by which gemfibrozil

glucuronide inactivates the enzyme. Gemfibrozil glucuronide showed mechanism-based inhibition of CYP2C8 but not gemfibrozil itself [43].

CYP2C9 is responsible for the metabolism of many clinically important drugs including diclofenac, celecoxib (COX 2 inhibitor, celebrex), ibuprofen, flurbiprofen, naproxen, piroxicam, mefenamic acid, glyburide, glipizide, glimepiride and tolbutamide, *S*-warfarin, *S*-acenocoumarol and phenprocoumon, sulfinpyrazone sulfide, torsemide and tienilic acid, candesartan, irbesartan, losartan, and phenytoin. It also metabolizes the endogenous substrates—arachidonic acid, linoleic acid, and serotonin. CYP2C9 is known to form the covalent adducts with the metabolites of tienilic acid, suprofen, and silybin (mechanism-based inhibitor), which in turn inactivates the enzyme [44]. In the presence of CYP2C9, tienilic acid first forms thiophene sulfoxide, which further reacts with water to give 5-hydroxytienilic acid and covalently binds to 2C9 [45]. Detail account of human 2C9 substrates, inducers, inhibitors, and their structure–activity relationship has been recently described by Zhou *et al.* [46].

CYP2C18 is known to play a minor role in drug metabolism. Substrate specificity of CYP2C18 substantially overlaps with other CYP2C enzymes [41]. Tienilic acid derivative with terminal O (CH₂)₃OH functional group is known as *CYP2C18 probe substrate* [47]. CYP2C18 is possibly responsible for the hypersensitivity of phenytoin (commonly used antiepileptic drug) observed in the skin [48]. CYP2C19, the most important member of the CYP2C subfamily, metabolizes 5–10% of prescribed medications with a high degree of stereospecificity. For example, CYP2C19 metabolizes *S*-mephenytoin to hydroxymephenytoin but not the R-enantiomer. CYP2C19 also plays an important role in the metabolism of several proton pump inhibitors including omeprazole and lansprazole. This CYP also preferentially hydroxylates the R-enantiomer of omeprazole and S-enantiomer in case of lansprazole [49]. Many other marketed drugs, including pantoprazole, diazepam, imipramine, and proguanil, are metabolized by CYP2C19. CYP2C19 is highly polymorphic and as many as 20% of Asians are thought to be deficient in CYP2C19 activity.

2.5.1.6 CYP2D Subfamily. CYP2D6 is the only one enzyme of CYP2D family and expressed in various tissues including liver, kidney, placenta, brain, breast, lung and intestine. CYP2D7 and CYP2D8 are inactive pseudogenes [50]. Although CYP2D6 is expressed at a low level in human liver, accounting for about 5% of the total P450 protein, it is, nevertheless, involved in the metabolism of ~12% of the marketed drugs. It is one of the best-studied P450s that exhibits polymorphism at the genomic level. Approximately 7–10% of the Caucasian population shows an inherited deficiency in this enzyme because of the presence of one or several mutant alleles at the CYP2D6 gene locus. The best-known examples of CYP2D6-related polymorphism are sparteine and debrisoquine [51], which are metabolized at different rates among individuals. Depending on the genetic variation, response to the drugs varies. Accordingly, these individuals are categorized into four genotypes, such as poor metabolizers (PMs), intermediate metabolizers (IMs), extensive metabolizers (EMs), and ultrarapid metabolizers (UMs). The genetic differences in CYP2D6 are associated with risk for disease like Parkinson's disease, lung cancer, liver cancer, and melanoma [52]. Substrates of CYP2D6 include bufuralolol, dextrometorphane, nortriptyline, propranolol, and several other drugs. Quinidine is a well-known potent selective inhibitor of the CYP2D6.

2.5.1.7 CYP2E Subfamily. CYP2E1 is the only gene of this family and containing ~6% of total human P450 in the liver. It is involved in the metabolism of ~3% of marketed drugs. CYP2E1 is expressed in many tissues including liver, lung, kidney, bone marrow, lymphocytes, and oropharynx (exposed to airborne xenobiotics). It has a dual physiological role both in detoxification and in nutritional support. CYP2E1 was first identified as the microsomal ethanol oxidizing system. It contributes to the metabolism of ethanol and also catalyzes the biotransformation of a large number of halogenated alkane and nitrosamines including aniline, chloroxazone, lauric acid, and 4-nitrophenol [53]. The inducibility of CYP2E1 by ethanol has been reported to occur both in humans and animals. Upregulation of CYP2E1 plays a useful physiological role during starvation/low carbohydrate diet by its capacity to metabolize fatty acid and ability to convert ketone to glucose [54]. Disulfiram and diethyldithiocarbamate are well-known mechanism-based inhibitors of CYP2E1 in humans.

2.5.1.8 CYP3A Subfamily. The CYP3A subfamily is the one of most abundant (~28% of total P450 content) and important drug-metabolizing enzymes. Human CYP3A has been shown to catalyze the metabolism of ~38% of all marketed drugs. In man, CYP3A has four known family members such as CYP3A4, CYP3A5, CYP3A7 and CYP3A43. CYP3A4 is expressed in liver, stomach, lung, intestine, brain, skin, and renal tissues. CYP3A4 expression levels are higher in both liver and small intestine where it metabolizes a large number of therapeutic popular drugs, which includes acetaminophen, codeine, cyclosporine, diazepam, erythromycin, lidocaine, lovastatin, taxol, warfarin, and many more. CYP3A4 has been well studied for its induction or inhibition because of drug–drug, drug–herbal, and drug–food interactions. For example, terfenadine, cisapride, and astemizole (withdrawn 2004) cause ventricular arrhythmias when CYP3A4 inhibitors such as ketoconazole or erythromycin taken along with these drugs. Mibefradil (posicor) is a known mechanism-based inhibitor of CYP3A4. In the small intestine, CYP3A4 plays a major role in the first-pass metabolism (presystemic clearance) of xenobiotics. Catalytic activity of CYP3A4 decreases longitudinally along the small intestine. Generally, the CYP3A4 concentrations in intestine are 10–50% lower than liver [55]. CYP3A4 has large active sites that can interact with two drugs simultaneously [56]. Popular drugs such as testosterone and midazolam both can interact in two distinct sites of CYP3A4 called the *steroid* and *benzodiazepine* sites, respectively. Although both CYP3A4 and CYP3A5 are expressed in liver and intestine, CYP3A5 is the predominant form expressed in extrahepatic tissues. CYP3A5 expression is polymorphic; five allelic variants of CYP3A5 have been reported [57]. There is some ambiguity in reports of the relative rate of drug and steroid metabolism by CYP3A4 and CYP3A5 [58], but an extensive study of recombinant enzymes with 14 compounds showed CYP3A4 was subject to greater inhibition than CYP3A5 [59]. CYP3A7 and CYP3A43 both play a minor role in drug metabolism. CYP3A7 is a fetal enzyme and is involved in the activation of drugs to teratogenic metabolites and CYP3A43 expressed in liver but has very low or restricted activity (0.2–5%) [60].

2.5.1.9 CYP4 Family. CYP4 family consists of 24 subfamilies (CYP4A–CYP4Z), which are expressed in both mammals and insects. This family mainly metabolizes fatty acids and/or eicosanoids. These enzymes oxidize mostly at the terminal methyl group (ω -hydroxylation) and, to a lesser extent, at the methylene group (ω -1 position). For example, CYP4F2 in human and CYP4A2 in rat catalyze hydroxylation of AA

to 20-hydroxyeicosatetraenoic acid (20-HETE), which causes hypertension and subsequently influence renal vascular and tubular functions [61,62]. Humans express 12 members of the CYP4 family, namely, CYP4A11, 4A22, 4B1, 4F2, 4F3, 4F8, 4F11, 4F12, 4F22, 4V2, 4X1, and 4Z1. CYP4A11 is a major hepatic enzyme in humans. It mainly catalyzes the ω - and ω -1-hydroxylation of various fatty acids such as lauric, myristic, and palmitic acid, and it has limited activity toward prostaglandins [63]. CYP4F2 and CYP4F3 were also identified in the human liver. Both have high specificity of ω -hydroxylation of leukotriene B₄. The immunosuppressant drug fingolimod and antiparasitic drug DB289 are predominantly hydroxylated by CYP4F [64,65]. The CYP4F2 in kidney also plays an important physiological role to produce 20-HETE, which effectively increases blood pressure. The elevated urinary 20-HETE and hypertension have been reported in Chinese populations with CYP4F2 variant [61].

2.5.2 Mouse CYP450 Enzymes

With good knowledge of mouse genetics and well-developed techniques for manipulating the genome of this species, the mouse is the most widely used animal model, in either native or genetically modified form, in pharmacology and toxicology and in the areas of pharmacokinetics and pharmacodynamics. This model is more practical and popular for research because of its low body weight, the rapid breeding time, and low maintenance costs compared with larger species. In mouse, ~90 functional CYP genes and ~21 pseudogenes with more than 80 enzymes are expressed and detected (www.drnelson.utm.edu/mouse). The major P450s from each subfamily involved in drug metabolism are listed in Table 2.1. The total P450 level in the liver is quite similar across commonly used mouse strains such as CBA, CD-1, and C57bl/6 [66].

CYP1A1/2 and CYP2E1 are also conserved and expressed in mouse. CYP1A2 is mainly expressed in the liver. The expression level of CYP1A1 in the liver is much lower than that of CYP1A2. Mouse CYP1A2 also specifically catalyzes phenacetin O-deethylation. The higher activity in male mice than female is attributed to relatively high expression level of CYP1A2 in the male mice [66]. Furafullyline selectively inhibits mouse CYP1A2, similar to human CYP1A2. Although mouse CYP2E1 is considered very conservative across species, however, some expression variability among different strains has been observed. The CD1 mouse has the lower level of CYP2E1 than other strains. Within two human CYP2E1 substrates, chlorzoxazone and *p*-nitrophenol, the latter seems to be a more specific substrate for mouse CYP2E1 because mouse CYP3A is also involved in 6-hydroxylation of chlorzoxazone.

In the mouse CYP2A subfamily, four members have been identified, CYP2A2, CYP2A5, CYP2A12, and CYP2A22. CYP2A5 shows the highest similarities to human CYP2A6 and CYP2A13 in amino acid sequence and substrate specificity. Like CYP2A6, it is mainly expressed in liver, kidney, brain, and olfactory mucosa [67]. It exhibits a high catalytic activity on 7-hydroxylation of coumarin and shares substrate pool of human CYP2A6, including testosterone, nicotine, cotinine, and carcinogenic nitrosamines [68]. CYP2A24 has high sequence similarities to CYP2A5 but its activity seems lower than CYP2A5. It is expressed mainly in the liver and dominant in the female mouse. The function of other two members in CYP2A subfamily is still unknown.

In mouse CYP2B subfamily, CYP2B9 and CYP2B10 are two major enzymes. CYP2B9 is dominant in female mice and its levels are negligible in male mice at

the age of about 13 weeks. CYP2B10 is detected in the liver and intestine in both male and females. The specific probe substrate of human CYP2B6 seems not to be as useful for mouse CYP2B enzymes. For example, 7-ethoxy-4-trifluoromethylcoumarin was specifically dealkylated by human CYP2B6, but this dealkylation activity in mouse liver microsomes appears not correlated with CYP2B enzyme level [66]. CYP2B19 is highly expressed in the outer, differentiated cell layers of mouse epidermis and plays an important role controlling epoxyeicosatrienoic acid formation [69]. Mouse CYP2B subfamily is inducible by andrographolide and nonylphenol [70].

Like human and rat, the mouse has the largest number of members in CYP2C subfamily including CYP2C29, 2C37, 2C38, 2C39, 2C40, 2C44, 2C50, 2C54, 2C55, and unpublished enzymes. CYP2C29, 2C37, 2C38, 2C39, 2C44, 2C50, 2C54, and 2C55 are expressed in the liver and CYP2C37 is the most abundant. The common CYP2C substrate tolbutamide is catalyzed by CYP2C29, CYP2C37, CYP2C38, and CYP3C39, but not by CYP2C44. Mouse CYP2C38 and CYP2C39 are two closely related enzymes with 92% amino acid sequence identity but they do not share similar catalytic activity. Mouse CYP2C39 specifically catalyzes 4-hydroxylation of retinoic acid and control this acid level in the liver [71]. Several CYP2C enzymes, including CYP2C50, 2C54, and 2C55, play an important physiological role by oxidizing AA and linoleic acid to regio- and stereo-specific epoxy- or hydroxymetabolites [72]. CYP2C40 is abundant in kidney and intestine. Most mouse CYP2C enzymes, such as CYP2C37 and CYP2C29, are inducible by phenobarbital and phenytoin via CAR. CYP2C44 has the lowest similarity (50–60%) of amino acid sequence to other enzymes and is mainly responsible for the metabolism of AA to 11,12-epoxyeicosatrienoic acids, which increases sodium renal uptake and blood pressure. It is not inducible by phenobarbital.

At least nine mouse CYP2D genes (Table 2.1) have been discovered. The expression level and enzyme function on most of them remains unknown [73]. CYP2D22 is one of the most abundant CYP2D enzymes in the mouse liver [74] and shows 77% identity to amino acid sequence of human CYP2D6, although it appears to have different substrate specificity and inhibition property [75].

In the mouse CYP3A subfamily, six members have been identified (Table 2.1). CYP3A11, CYP3A25, and CYP3A41 are predominantly expressed in the liver, while CYP3A13 is expressed more in the intestine than liver [76]. Among them, CYP3A11 has the closest similarity (75%) to amino acid sequence of human CYP3A4 and catalyzes testosterone 6 β -hydroxylation as well [77]. The female mouse has higher testosterone 6 β -hydroxylation activity than male mouse across most common strains [66] due to higher expression levels of CYP3A41 and 3A44 in female than male mouse [78]. The mouse CYP3A11, not CYP3A13, is inducible by phenytoin and dexamethasone.

CYP4A10, CYP4A12, and CYP4A14 were identified in mouse liver and kidney. They are homologs of rat CYP4A1, 4A8, and 4A2/3, respectively. Like other CYP4A members, they catalyze the oxidation of fatty acid and eicosanoids. CYP4A12, with 75% amino acid sequence identity to human CYP4A11, has the highest 20-HETE synthase activity, which regulates renal blood pressure. The disruption of CYP4A14 gene in mouse results in increase of androgens in plasma and CYP4A12 expression level in the kidney, ultimately causing hypertension [79]. On the other hand, the disruption of CYP4A10 gene in mouse causes increase of CYP2C44 expression or its mediated epoxyeicosatrienoic acids formation, which activates kidney epithelial sodium channel, and ultimately increase sodium reabsorption and blood pressure [80]. CYP4A10

and CYP4A14 were highly inducible in the liver and kidney of both genders by peroxisome proliferator, methylclofenapate. However, CYP4A12 is sexually dimorphic. Methylclofenapate induces the transcription of CYP4A12 in the liver of female mice but reduces the enzyme level in the liver of male mice [81].

2.5.3 Rat CYP450 Enzymes

More than 90 cytochrome P450 enzymes have been identified in rats from P450 genes and pseudogenes (<http://drnelson.utmem.edu/CytochromeP450.html>). Major P450 enzymes involved in the metabolism belongs to same P450 subfamilies as humans. Each rat enzyme is summarized in Table 2.1. The relative abundance of major CYP enzymes in the liver is shown in Fig. 2.10b. The expression level of CYP2C is dominant in adult rat and the contents of CYP2A, CYP2C, and CYP3A are sex dependent. Adult male rats expressed CYP2C11 and CYP3A2 as the major isoforms. However, adult female rats mainly expressed CYP2C12 and did not have CYP2C11 or CYP3A2.

Two isoforms of CYP1A subfamily, CYP1A1 and CYP1A2, are well conserved in mammalian species. Similar to humans, CYP1A2 in rats is mainly located in the liver and the relative expression levels are lower than those of humans. CYP1A1 is almost undetectable in the liver but is dominant in other tissues such as small intestine [82]. Rat CYP1A1 and CYP1A2 shared similar substrates as humans, catalyzing PAHs and carcinogenic heterocyclic amines. Subtle difference in catalytic activity and enzyme inhibition of CYP1A2 exists between human and rat. For example, human CYP1A2 does not show any selectivity for the metabolism of 7-methoxy or 7-ethoxyresorufin, whereas rat CYP1A2 preferentially catalyzes the O-dealkylation of 7-ethoxyresorufin. Both human and rat CYP1A2 enzymes have high catalytic affinity for phenacetin O-deethylation. Furafylline is a potent mechanism-based inhibitor of human CYP1A2, while it shows 40-fold less inhibition for rat CYP1A2 [83]. Rat CYP1A subfamily is also inducible by PAHs, cruciferous vegetables, cigarette smoke, and drugs at variable extent through the Ah receptor. The antiulcer drug, omeprazole, has been reported to specifically induce human hepatic CYP1A enzymes but its inducible effects were not observed in rodents [84,85].

Like CYP1A1, rat CYP1B1 is constitutively expressed mainly in extrahepatic tissues such as lung and adrenal glands. Interestingly, both rat and human CYP1B1 have 80% homology in their amino acid sequences. Both human and animal forms are involved in metabolic activation of PAHs to reactive metabolites, which are associated with mutagenesis and carcinogenesis [30,86]. CYP1B1 is also inducible through Ah receptor.

The rat CYP2A subfamily contains CYP2A1, CYP2A2, and CYP2A3. CYP2A1 is expressed in the liver of male and female rats, and the expression level decreased in mature rats [87]. The expression of rat CYP2A1 is regulated by the growth hormone. CYP2A2 is exclusively expressed in adult male rats [88]. The total CYP2A1/2 contribution is ~2% of the total CYP contents in the liver. Although CYP2A1 and CYP2A2 show 60% amino acid sequence homology to human CYP2A6, they have different substrate specificity. The endogenous steroids are major substrates of rat CYP2A, while human CYP2A6 mainly catalyzes the metabolism of many xenobiotics but not steroids. For example, CYP2A1 and CYP2A2/3 catalyze the 7 α - and 15 α -hydroxylation of testosterone, respectively. CYP2A1 is inducible by phenobarbital and

3-methylcholanthrene, while CYP2A2 is not. Rat CYP2A3 is an extrahepatic enzyme and predominantly expressed in the olfactory mucosa and at relatively low levels in the lung [89]. CYP2A1 and CYP2A2 appear not to metabolize foreign molecules; in contrast, CYP2A3 activates 4-nitrophenol, hexamethylphosphoramide (a nasal procarcinogen), and 2, 6-dichlorobenzonitrile to cause tissue-specific toxicity in the olfactory mucosa of rodents.

The rat CYP2B subfamily contains three isoforms, CYP2B1, CYP2B2, and CYP2B3, and they share ~75% homology with the human CYP2B6. The expression level of CYP2B in the rat was relatively low and contributes to <5% total CYP content in the liver. It is expressed in hepatic and other tissues [90] and mainly involved in the metabolism of foreign molecules. CYP2B1 and CYP2B2 shared 97% amino acid sequence homology with very similar substrate specificities. In most cases, substrates overlap with those of human CYP2B6. For example, testosterone and lidocaine are oxidized by CYP2B1/2 and CYP2B6. CYP2B subfamily activates many compounds such as anticancer drugs, cyclophosphamide, and ifosfamide [91,92] and natural carcinogens such as aflatoxin B₁. The expression of CYP2B is regulated by hormones and glucocorticoids, which may lead to different CYP2B levels between male and female rats [93]. Like CYP2B6, CYP2B1 and CYP2B2 were induced via CAR and PXR.

Like human CYP2C subfamily, multiple CYP2C enzymes, such as CYP2C6, CYP2C7, CYP2C11, CYP2C12, CYP2C13, CYP2C22, and CYP2C23, are expressed in rats. This subfamily comprises of about ~50% of the total CYPs in liver [87]. In contrast to humans, the expression of CYP2C enzymes in rats is sex dependent. CYP2C11 and CYP2C13 are expressed in the liver of only male rats while CYP2C12 is expressed only in the liver of mature female rats. CYP2C enzymes are also expressed in extrahepatic tissues such as kidney, brain, and intestine but at lower levels [94–96]. CYP2C6 is not sex specific and expressed in relatively low levels in liver and intestine. CYP2C23 is expressed mainly in rat kidney and plays an important role in the metabolism of eicosatrienoic acid to form 11,12-epoxyeicosatrienoic acid and hydroxy-eicosatrienoic acid, which are involved in the regulation of renal vascular tone and salt excretion [97]. CYP2C enzyme catalyze a variety of compounds including endogenous compounds such as testosterone and foreign molecules such as diclofenac, (-)-verbenone [98], and perfluoro-octanesulfonic acid derivatives [99]. CYP2C6 is inducible by phenobarbital, while other isoforms are not inducible.

Six enzymes (CYP2D1, CYP2D2, CYP2D3, CYP2D4, CYP2D5, and CYP2D18) have been identified from *CYP2D* gene subfamily in the rat. Like human CYP2D6, this subfamily is expressed in various tissues such as liver, kidney, and brain [100]. Among these enzymes, CYP2D1 exhibits close homology of human CYP2D6, catalyzing similar substrates such as bufuralol and debrisoquine. Bufuralol 1'-hydroxylation and 8-hydroxylation of mianserin are catalyzed by most CYP2D enzymes, and CYP2D2 showed the highest affinity to bufuralol 1'-hydroxylation [101,102]. The substrate specificity of other rat CYP2D enzymes remains unknown.

CYP2E1 is a conservative P450 enzyme across species. Rat CYP2E1 shows more than 80% amino acid sequence homology to human CYP2E1 and represents ~10% P450 contents in the liver. Similar to human, rat CYP2E1 is capable of activating nitrosamines and many organic volatile procarcinogens such as benzene, carbon tetrachloride, and chloroform. The rat seems to be the best model for evaluating CYP2E1 activity in the human. It is also inducible by acetone and ethanol.

CYP3A1 (3A23), CYP3A2, CYP3A9, CYP3A18, and CYP3A62 have been identified from *CYP3A* gene subfamily in rats. The expression of these enzymes appears to be sex dependent and regulated by growth hormones in a similar manner as other sexually dependent rat P450s [103,104]. CYP3A1 and CYP3A18 are male dominant while CYP3A9 is female dominant in the liver [105]. Rat CYP3A2 is equally expressed in both male and female rat liver at the young age, but it is expressed exclusively in male rat liver at their adult stage [87]. In contrast to humans, rat *CYP3A* subfamily represents only ~20% P450s in rat liver. CYP3A62 is dominant P450s in the rat intestine. Rat CYP3A1, CYP3A2, CYP3A9, and CYP3A62 show 71–75% similarity in amino acid sequence of human CYP3A4 and CYP3A5 [104]. 6 β -Hydroxylation of testosterone and 1- and 4-hydroxylation of midazolam are common substrates for all CYP3A forms. However, some human CYP3A substrates such as nifedipine are not catalyzed by rat CYP3A [33]. Unlike human CYP3A, rat CYP3A is not inhibited specifically by ketoconazole [83]. The species difference in mechanism-based inhibition of CYP3A has also been reported [106]. Human CYP3A can be induced by both rifampin and dexamethasone, while rat CYP3A was induced by dexamethasone only [84].

The rat CYP4A subfamily has similar catalytic properties as human CYP4A. It oxidizes both endogenous and foreign compounds, including steroids, fatty acids, leukotriene B₄, and AA. Rat CYP4A1–3 enzymes are present mainly in the liver and share 72–96% amino acid sequence similarity with human CYP4A11 [107]. They mainly catalyze ω -1 and ω hydroxylation of fatty acids and the substrate specificity and ω -regioselectivity appear different from human CYP4A [63]. Rat CYP4F1 is expressed predominantly in liver and kidney and, catalyzes hydroxylation of leukotriene B₄ and AA, similar to human CYP4F [108].

2.5.4 Dog CYP450 Enzymes

The dog is another animal species used in pharmacokinetic and toxicology studies during the development of both human and veterinary medicines. It possesses the same subfamily of CYP450 enzymes including CYP1A1/2, 2A13, 2A25, 2B11, 2C21, 2C41, 2D15, 3A12, and 3A26. The expression levels of major CYP enzymes in male dog liver are shown in Fig. 2.10c [109]. Like other species, although dog CYP450 isoforms show a high degree of similarity in amino acid sequence to homologs of human CYPs, their enzyme activity and specificity are not always the same.

CYP1A1/2 is present relatively in low levels (~4%) in the dog liver and has 84% similarity in amino acid sequence. Ethoxyresorufin and phenacetin are good substrates for dog CYP1A1/2, but it does not catalyze other human CYP1A2 substrates such as caffeine, theobromine, and estradiol [110]. Dog CYP1A1/2 is also inducible by PAHs such as β -naphthoflavone and 3-methylcholanthrene [111].

Dog CYP2A13 and CYP2A25 are expressed in the liver while human CYP2A13 is mainly expressed in respiratory tissues, including nasal mucosa, trachea, and lung. Human CYP2A13 catalyzes tobacco-related *N*-nitrosamines efficiently [112] but little is known about the substrate of dog CYP2A subfamily.

Unlike human CYP2B6 or rat CYP2B1, CYP2B11 is predominant in the dog liver and comprises 10–20% of total CYP450 contents. Similar to rat CYP2B1, dog CYP2B11 also catalyzes the hydroxylation of 16 α - and 16 β -testosterone [113]. Dog CYP2B11 is induced by phenobarbital and it also activates anticancer prodrugs,

cyclophosphamide and ifosfamide. Although it shares ~78% similarity in amino acid sequence to human CYP2B6 [114], CYP2B11 has the different substrate specificity. For example, it catalyzes 4'-hydroxylation of mephenytoin and N-demethylation of dextromethorphan, which are mainly catalyzed by human CYP2C19 and CYP3A, respectively. *N*-(α -Methylbenzyl)-1-aminobenzotriazole is identified as a potent mechanism-based inhibitor of CYP2B11 [115].

CYP2C21 and CYP2C41 have been identified in dog liver and both comprise ~20% total P450 contents in liver. They exhibit 67–76% similarity in amino acid sequence to human CYP2C subfamily. 16 α -Hydroxylation of testosterone is catalyzed by CYP2C21 [116]. However, specific human CYP2C9 and CYP2C19 substrates, *S*-warfarin and mephenytoin, respectively, are not catalyzed by dog CYP2Cs; instead, they are catalyzed by dog CYP3A12 and CYP2B11, respectively [117]. CYP2C41 is more homologous to human CYP2Cs than CYP2C21. The unique polymorphism of CYP2C41 in dog liver was observed and this enzyme was found only in 10–16% of the tested dogs, which may provide variability of metabolic clearance in dogs when compounds are metabolized by CYP2C subfamily [118].

CYP2D15 is expressed in dog liver and comprises ~10% of total P450 contents. Its enzymatic activity is similar to human CYP2D6. Two typical human CYP2D6 catalytic reactions are bufuralol 1'-hydroxylation and dextromethorphan O-demethylation, mainly used for monitoring enzymatic activity of dog CYP2D15 [116]. It is also selectively inhibited by quinidine [119]. The cDNA of dog CYP2E1 was first cloned in 2000 [120], and its activity seems to be similar to human CYP2E1.

CYP3A12 and CYP3A26 are two identified dog CYP3A isoforms and comprise ~15% of total P450 contents in the liver. CYP3A12 shares about 80% similarity in amino acid sequence of human CYP3A4, and it selectively catalyzes 6 β -hydroxylation of testosterone. The catalytic activity of CYP3A12 is also inhibited by ketoconazole and troleandomycin. Dog CYP3A12 is reported to catalyze other human CYP subfamily substrates such as diazepam, dextromethorphan, and *S*-warfarin [116,117]. CYP3A26 shares similar substrates as CYP3A12, but its catalytic activity seems to be less than CYP3A12 [121]. The mRNA expression level of CYP3A26 is higher than CYP3A12 in the liver but lower in the duodenum [122]. Both enzymes are inducible probably via PXR but ligands seem have different binding specificity on human and dog PXR [123]. CYP3A12 is inducible by rifampin but not by dexamethasone while both ligands can induce human CYP3A4. Ketoconazole is identified as potent and selective reversible inhibitor of CYP3A12 with K_i at 0.13–0.33 μ M.

2.5.5 Monkey CYP450 Enzymes

The monkey is commonly chosen as a nonhuman primate to conduct pharmacology, toxicology, and pharmacokinetic studies. Cynomolgus monkeys (*Macaca fascicularis*) and rhesus monkeys (*Macaca mulatta*) are commonly used. CYP1A, CYP2B, CYP2C, CYP2D, CYP2E1, and CYP3A subfamilies have been characterized in monkeys, similar to humans and rats. The expression levels of major P450 enzymes in untreated monkey are shown in Fig. 2.10d [124,125]. The characteristics of these P450 enzymes described here are mainly obtained from cynomolgus monkeys. Most of these CYP enzymes show a high sequence identity (>93%) to the homologous of human CYPs and metabolize all the typical substrates of the corresponding human CYP subfamily [126].

CYP1A1/2 and CYP2E1 are well conserved and expressed in the monkey. Homologies of these enzymes between human and monkey reached above 94% in amino acid sequences [127]. In contrast to human and rat, CYP1A1 content is higher than CYP1A2 in the monkey liver [128]. Catalytic activities of these enzymes are very similar to those of the human. Monkey CYP1A1, CYP1A2, and CYP2E1 catalyze the 7-ethoxycoumarin O-deethylation, phenacetin O-deethylation, and chlorzoxazone 6-hydroxylation, respectively, similar to other species. Surprisingly, monkey CYP1A2 is not inhibited by furafylline [119].

Monkey CYP2A family contains CYP2A23 and CYP2A24. Both exhibit above 95% similarity in amino acid sequence of human CYP2A6. Both catalyze 7-hydroxylation of coumarin, a typical CYP2A substrate.

CYP2B17 is the only one identified CYP2B enzyme in the monkey. It exhibits >94% similarity in amino acid sequence to human CYP2B6 and similar catalytic activity to pentoxyresorufin O-dealkylation [126].

The monkey CYP2C subfamily comprised of four members, CYP2C20, CYP2C43, CYP2C75, and CYP2C76. CYP2C20 has a high sequence identity and enzymatic activity to human CYP2C8. It shows 92% identity of amino acid sequence of CYP2C8 and catalyzes the same substrate, paclitaxel. CYP2C43 has both 93% and 91% sequence identity to human CYP2C9 and CYP2C19, respectively. CYP2C43 catalyzes 21-hydroxylation of progesterone and 4'-hydroxylation of *S*-mephenytoin, similar to human CYP2C19, but it does not catalyze the human CYP2C9 substrate, tolbutamide. Therefore, CYP2C43 appears functionally related to human CYP2C19. CYP2C75 has 92–93% sequence identity to human CYP2C9 and CYP2C19. In contrast to other CYP2C isoforms, monkey CYP2C76 exhibits only ~70% similarity of amino acid sequence of other human and monkey isoforms [129]. It also catalyzes the tolbutamide 4-hydroxylation and testosterone 2 α -hydroxylation but at a relatively lower rate compared to CYP2C75.

The monkey CYP2D subfamily is comprised of five enzymes but each enzyme is expressed in different strain. CYP2D17 is expressed in the liver of cynomolgus monkey and has 93% identity of amino acid sequence to human CYP2D6. It catalyzes 1'-hydroxylation of bufuralol at higher activity than human CYP2D6 [126]. CYP2D19 and CYP2D30 were identified in the liver of different female marmosets, and they showed homologies of 93% in their amino acid sequence. CYP2D30 exhibits selective 4-hydroxylation of debrisoquine and stereoselective 1'(S)-hydroxylation of bufuralol, similar to human CYP2D6. In contrast, CYP2D19 prefers catalyzing 5,6,7,8-hydroxylation of debrisoquine and 1'(R)-hydroxylation of bufuralol [130]. Whether both isoforms exist in the same marmoset liver remains unknown. CYP2D29 was found in Japanese monkeys (*Macaca fuscata*) and has 96% identity of amino acid sequence to human CYP2D6. The variant CYP2D42 was detected in the rhesus monkey.

CYP3A8 is a major enzyme of monkey CYP3A subfamily. It has 93% identity of amino acid sequence to human CYP3A4 and represents ~20% of total P450 contents in the liver. Like CYP3A4, it catalyzes 6 β -hydroxylation of testosterone, 1'-hydroxylation of midazolam, and N-demethylation of erythromycin. Since total P450 content per milligram liver microsomes protein ratio is higher in monkeys than in humans, CYP3A8 has four to five times higher catalytic activity than CYP3A4. Other enzymes of the human 3A subfamily, namely, CYP3A5, 3A7, and CYP3A43 were also reported in the monkey [131].

CYP4A11, CYP4F2, CYP4F3v2, and CYP4F11/12 are also detected in liver, jejunum, and kidney of monkeys. Their cDNAs are highly identical to human homology and assumed to have similar functions.

2.6 ETHNIC VARIABILITY IN EXPRESSION AND ACTIVITY OF CYTOCHROME P450 ENZYMES

As discussed earlier, one of the major factors influencing a patient's response to any medication is drug metabolism. The metabolism of a drug is governed primarily by the P450s and many of these enzymes show genetic polymorphism, which can affect the levels of their expression and catalytic properties. Therefore, ethnic variations and polymorphisms in P450 enzymes have been used to predict drug metabolism/toxicity, efficacy, and selection of doses. Optimization of genetic basis for the difference in drug responses is crucial to address the ethnic variation in P450 activity.

There are wide varieties of drugs that have shown a good correlation between decreased drug clearance/decreased activity of metabolizing enzymes and their adverse reactions after normal doses. It is now well known that genetic variation provides the molecular basis of variability in drug-metabolizing enzymes mostly 2C9, 2C19, 2D6, and 3A. There are at least three categories in genetic variation (i) UMs, which metabolize substrate so quickly because of gene duplication. This is so effective in maintaining high drug clearance, that therapeutic levels often cannot be reached in clinical practice in these individuals; (ii) PMs, these inherit genetic material that is devoid of effective enzyme expression, which results in a lack of metabolism of CYP substrates; and (iii) IMs, these are heterozygotes with partial expression of appropriate CYPs, which result in intermediate drug clearance. The most severe side effects are often noticed with IMs and PMs, and substrates that require metabolic activation may demonstrate suboptimal clinical efficacy.

CYP2D6 polymorphism is of the major concern as many of the antipsychotic drugs possess narrow therapeutic indices and are primarily metabolized by CYP2D6. Approximately 7–10% of Caucasians, 0–5% Africans, and 0–1% Asians lack CYP2D6 activity because of the presence of one or several mutant alleles at the *CYP2D6* gene locus, and these individuals are known as *PMs*. This results in a poor response to codeine therapy, for example, because of their low formation of the active metabolite, morphine, catalyzed by CYP2D6. Compared with IMs or UMs, PMs demonstrate markedly greater AUC values for parent drugs that are metabolized by CYP2D6, and therefore require lower doses to achieve therapeutic effects. Codeine metabolism is considerably lower in Chinese than in Caucasian individuals [132]. Another study showed that codeine's clearance via O-demethylation is significantly higher in white Americans than in Chinese. Indeed, with coadministration of a CYP2D6 inhibitor, quinidine, the production of morphine is markedly greater in Caucasians than in the Chinese population [133].

Other polymorphic P450 enzymes are CYP2C9 and CYP2C19. Approximately 20% of Asians and 3% Caucasians are PMs of CYP2C19 [134,135]. The patients carrying allelic variants CYP2C9*6 or CYP2C19*2 are shown to be susceptible to neutropenia in the treatment of anticancer drug indinavir, which is metabolized primarily by CYP2C9 and 2C19. Caucasian patients require higher warfarin (metabolized by CYP2C9) doses than Asians to attain a comparable anticoagulant effect. Conversely, Chinese patients

need 50% lower average doses than the Caucasians patients. The average maintenance dose for Japanese patients is also much lower than for US patients [133]. Pharmacokinetic studies of diazepam, a substrate of CYP2C19, showed higher clearance for Caucasians relative to Asians, while levels of desmethyldiazepam, the major active metabolite higher in Asians [136]. Clopidogrel, an antiplatelet prodrug, is activated by CYP2C19. CYP2C19 PMs are at high risk of treatment failure with clopidogrel [137]. There are tremendous variations in responsiveness to metabolic activation of clopidogrel attributed from genetic differences. The FDA has shown concern (a black box warning) about clopidogrel's efficacy in patients who are PMs of CYP2C19, which may influence estimated 2–14% American and almost 50% of Asian population.

Several drugs have shown the ethnic variability in drug response, and there is no clear FDA guidance requiring pharmaceutical companies to conduct clinical studies in different population. Personalized drug therapy based on genetic information will improve drug efficacy and reduce adverse drug reactions. Currently, therapeutic drug monitoring approach is focused on the pharmacogenetic information of patient to optimize dose regimens in a noninvasive manner before drug administration. Kim *et al.* [138] have recently reported a detailed study using a decision matrix, which included ethnic frequency of clinically relevant polymorphic P450 enzymes, metabolic profiles, and adverse drug reactions. This is termed as the *pharmacogenetic drug monitoring (PDM) system*. The system facilitated the identification of 17 drugs for which PDM provides the greatest potential benefit at one Korean Hospital. The disadvantage of the system particularly for pharmaceutical company is that it will be more time consuming and expensive to develop drugs and doses depending on the ethnic variability. It has been proposed to use genetic test of CYP2C19 to choose right patients of clopidogrel and provide alternative treatment for PM patients of CYP2C19. However, the long genetic test time (normally three days) prevents its practical use from the acute coronary syndrome treatment drugs such as clopidogrel, which is required immediately for patients. The alternative druglike ticagrelor does not have genetic polymorphism issue and could be favored by patient if genetic tests are required for clopidogrel.

2.7 TOOLS FOR *IN VITRO*–*IN VIVO* EXTRAPOLATION

Since the significant difference exists in the enzyme expression and catalytic activities of P450 between humans and animals, it brings challenges to understand if drug-metabolism-associated toxicities in preclinical species are relevant to humans and the safety assessment of human metabolites is properly covered in preclinical species used for safety assessment of drug candidates. Many valuable tools have been developed to extrapolate metabolism and toxicity in animals to humans. *In vitro* system, human liver microsomes, recombinant human P450 enzymes, human hepatoma-derived cell lines (HepG2), and cultured human hepatocytes are routinely used in preclinical studies to determine metabolic profiles, potential drug–drug interactions, induction/inhibition, polymorphic metabolism, and P450-mediated genotoxicity of new drug candidates. *in vivo*, genetically modified mice have also been used for assessing the drug-metabolizing enzymes and drug-induced toxicity. This section briefly describes the application of each system and their limitations.

Human liver microsomes and recombinant human CYP isoforms expressed in baculovirus-insect cells are widely used to conduct inhibition studies and phenotyping

of P450s. These assays are relatively easy to handle, offer high throughput capability, and are widely used for the mechanistic studies on P450 catalytic activities. However, these assays have limitations, because the integral cell environment is disrupted and the result may not reflect the real function of P450s *in vivo*.

Primary culture of human hepatocytes usually cultivates cells between two layers of collagen (sandwich culture); therefore, both biological functions and morphology of liver are preserved. Thus, primary culture of human hepatocytes is currently considered the closest *in vitro* model to predict functions of P450s and other drug-metabolizing enzymes *in vivo*. It has been used for metabolic stability, drug induction studies, and gene-expression-based hepatotoxicity of new drug candidates [139]. However, the donors of primary human hepatocytes are unavoidably variable because of intrinsic individual differences; therefore, the expression levels and enzymatic activities of P450s could be different from study to study. Meanwhile, hepatic functions decline within few hours under conventional culture conditions [140]. The liver slices have the closest resemblance to *in vivo* cytoarchitecture and their functionality is also close to the situation *in vivo*. However, its short life time (~ 1 day), individual variability, and erratic supply of human liver tissue limit its applications.

Recently, a microscale culture system has been developed for human liver cells. This micropatterned system maintained hepatocytes morphology and functions for several weeks [141]. Thus, this system may provide more reliable information on metabolic profiles, P450 induction, and hepatic toxicity of new drug candidates.

Human hepatoma-derived cell lines such as HepG2 cells are also frequently used as *in vitro* models for studying the metabolism and toxicity of drugs. The cells retain many liver-specific functions and have unlimited lifespan. However, they do contain very low levels of all major drug-metabolizing enzymes [142,143]. Thus, it is usually necessary to insert recombinant human P450 isoforms into the HepG2 cells in order for the catalytic activity and metabolic bioactivation of each human P450 to be studied. The international working group on genotoxicity testing recommended that the use of genetically engineered hepatoma cell lines stably expressing P450 enzymes is an optimized system because the P450s in traditional induced rat liver S9 did not resemble human P450s. This transfected HepG2 cell system could also identify the P450 isoform contributing the genotoxicity. The expression of single or multiple P450s at well-controlled level via adenovirus system suggests that transfected HepG2 cells could be used for P450 phenotyping, induction, and genotoxicity studies [144].

The recent genetically engineered mouse models, including transgenic and humanized models, provide potential to evaluate the role of human P450 enzymes and their relevance to toxicity *in vivo* [145]. In most cases, the transgenic models express human P450 enzymes on a wild-type mouse background; the knockout mice models often deactivate individual P450 in host mouse; and humanized models express human P450 enzymes in the absence of the host (mouse) P450 orthologs. For example, species difference in the acetaminophen-induced hepatotoxicity has been successfully demonstrated by using wild-type, *Cyp2e1*^(-/-), and humanized CYP2E1 mice [146]. At the dose of 400 mg/kg acetaminophen, all wild-type mice exhibited severe hepatic necrosis, and 9 out of 10 humanized CYP2E1 mice showed moderate centrilobular hepatotoxicity; however, the *Cyp2e1*^(-/-) mice had no detectable histological hepatic necrosis. These results suggest that CYP2E1 bioactivation was responsible for hepatotoxicity of acetaminophen, and human CYP2E1 appears less active than *Cyp2e1* in the induction of hepatotoxicity. So far six humanized mice models, which expresses individual

human CYP1A1, CYP1A2, CYP2E1, CYP2D6, CYP3A4, and CYP3A7 enzymes, have been developed [147]. Although these models mimic P450-mediated drug metabolism in humans, it is still difficult to quantitatively extrapolate metabolic information to humans because the expressed human P450 enzyme level, enzymes distribution in mice tissues, and physiology in humanized mice (such as hepatic blood flow) are still significantly different from those of humans.

2.8 SUMMARY AND FUTURE PERSPECTIVES

Cytochrome P450 enzymes play an important role in the metabolism of foreign molecules (drugs and environmental chemicals) and endogenous compounds. This large enzyme family with broad substrate diversity facilitates to eliminate xenobiotics from body and catalyze catabolism of endogenous compounds for their physiological functions. Over the past 20 years, our understanding of genes, structures, subfamily diversities, functions, and regulations of human P450s is considerably advanced and 30 crystal structures of 8 cytochrome P450s have been published [148]. This has resulted in much useful published literature and FDA guidance on P450 inhibition and its impact on drug–drug interactions. The accumulated knowledge of P450s has significantly improved the contribution of drug metabolism studies to the drug discovery and development.

Meanwhile, many questions and challenges on P450s and other drug metabolism enzymes still exist. The overwhelming substrate diversity of cytochrome P450s seems to arise from their intrinsic physiological roles to eliminate foreign molecules from body. Thus, their substrate specificity and inhibition selectivity are still not predictable, despite the availability of the crystal structures of these enzymes. The large scale screening of P450 substrates and inhibitors experimentally is, however, routine practice during the drug discovery. While the existence of P450 differences between human and animals is well recognized, how to extrapolate drug metabolism and associated toxicities in preclinical species to humans remains an important question in the pharmaceutical industry. The better understanding of involvement of P450s in rodent carcinogenicity studies on new chemical entities may improve prediction of human relevance.

The metabolic activities of human P450s *in vitro* have been well established, and their catalytic activity on new chemical entities and metabolite formation has been qualitatively predicted well *in vivo*. But quantitative predictions are still inaccurate, probably because of limitations in our knowledge of the interplay of P450s with other conjugating enzymes and transporters. The humanized animal models and living culture systems will have the potential to integrate drug metabolism enzymes and transporter interactions and differentiate species differences.

Knowledge of polymorphism of major human P450 has grown considerably in recent years. The genotype, age, sex, race, and environmental and personal lifestyle all influence P450's expression and function. Indeed, remarkable progress has been made in the understanding of on genetic polymorphism of P450s, such as CYP2D6 and CYP2C19. Personalized drug therapy based on P450 expression variation in patients is attempted to optimize dose regimen and subsequently improve drug efficacy [138]. However, there is still much to learn for the pharmaceutical industry in the design and

safe marketing of drugs of certain drugs in individual human populations, as well as the wider issue of personalized drug therapy.

ACKNOWLEDGMENT

The authors would like to thank Dr. Lewis Klunk for reviewing this chapter and providing insightful comments.

3.1 SUMMARY

Scientifically guided risk assessment and clinical pharmacologic evaluation of pharmacokinetic (PK) drug–drug interactions (DDI) are key components of contemporary drug development and play an integral role in the overall benefit/risk evaluation of new molecular entities (NMEs). DDI risk assessment and clinical evaluation should consider the potential for the NME to alter the PK of coadministered drugs (NME as the precipitant) and also the potential for coadministered drugs to alter NME PK (NME as the object). Risk assessment begins with *in vitro* and mechanistic studies of the NME's potential to alter drug disposition via inhibition or induction of drug-metabolizing enzymes and transport proteins, and additionally, studies that elucidate

the clearance mechanisms of the NME itself. This is followed by a mechanistic and quantitative translation of *in vitro* parameters to estimate clinical PK consequences of a potential DDI (i.e., expected increase in object drug exposure). When the risk for DDI cannot be definitively dismissed as low based on translational assessment from the results of *in vitro* studies, controlled clinical DDI studies are designed to evaluate the clinical pharmacologic correlates of the *in vitro* data. Finally, the results of clinical DDI studies will need to be interpreted in the context of knowledge of the therapeutic index of the object drug, gained from exposure–response understanding for both safety and efficacy endpoints. This chapter provides a technical overview and strategic perspectives on each of these aspects of DDI risk assessment and clinical evaluation, with the use of examples that illustrate applications in drug development and the translation of scientific knowledge to prescribing guidance, in the context of currently available regulatory guidance and published scientific opinion.

3.2 INTRODUCTION AND MEDICAL IMPORTANCE

DDI represent an important mechanism of adverse drug reactions making their evaluation a key element of contemporary drug discovery, development, and regulation, given their potential impact as an integral component of clinical therapeutics. DDI profiling and risk forecasting when incorporated into the overall framework of multidimensional optimization can help identify candidates with likely low clinical DDI risk in the discovery stage and subsequently enable development of rational clinical pharmacologic DDI evaluation strategies to manage risk in clinical drug development. Finally, the ultimate goal of nonclinical and clinical DDI studies is to permit integration of DDI knowledge acquired in the development phase into prescribing guidance in a manner that enables optimal postmarketing risk management following marketing authorization.

A clinically significant DDI occurs when the therapeutic or toxic effects of a medication are altered by administration with another drug. DDIs are broadly classified into two categories: (i) PK interactions wherein one drug alters the absorption, distribution, metabolism, or elimination of another coadministered drug resulting in altered blood/target organ levels and potential effects on efficacy and/or safety; and (ii) pharmacodynamic (PD) interactions wherein one drug alters the pharmacologic effect (efficacy and/or safety) of another coadministered drug without affecting its PK. This chapter discusses DDIs resulting from PK mechanisms, with a focus on metabolic interactions and approaches for risk assessment and clinical pharmacologic evaluation of such interactions in contemporary drug development.

The medical importance of DDIs, and, in particular, the need for scientifically guided premarketing risk evaluation can be readily appreciated from the results of a review of drugs withdrawn from the US market from 1998 through 2003 because of their involvement in major clinical DDIs with commonly coadministered agents [1]. A notable example is the calcium channel blocker mibefradil that was used in the medical management of hypertension and angina. Mibefradil, a strong mechanism-based inactivator of cytochrome P450 3A (CYP3A) and an inhibitor of the efflux transporter P-glycoprotein (P-gp) produced dangerous and occasionally fatal interactions with sensitive substrates of CYP3A, such as the calcium channel blocker felodipine. This led to

the United States Prescribing Information (USPI) for mibefradil to be revised to recommend the contraindication of concomitant use of 26 drugs spanning multiple therapeutic areas. Mibefradil was voluntarily withdrawn in June 1998 by the manufacturer within a year following approval because of recognition of these serious interactions produced by this drug and the complexity of prescribing information needed to administer the drug safely. Additionally, considering that other pharmacotherapeutic options without similar serious DDI risks were available for the medical management of the conditions for which the use of mibefradil was indicated, the overall benefit/risk ratio for mibefradil was unfavorable. This example illustrates the importance of early assessment of risk for NMEs to produce DDIs with coadministered agents via effects on their PK (e.g., via metabolic inhibition by the NME). Other notable examples of drug withdrawals due to unacceptable DDI liabilities include the nonsedating antihistamine drugs, terfenadine and astemizole, and the prokinetic agent cisapride that was used for the management of gastroesophageal reflux disease. All three drugs were associated with two common properties. These drugs were inhibitors of the ion channel hERG, which plays a critical role in cardiac repolarization, and were additionally cleared almost exclusively via metabolism by CYP3A such that large and clinically significant increases in their exposure could occur on coadministration of inhibitors of this enzyme. This combination of an unfavorable off-target pharmacologic effect associated with proarrhythmic risk and exquisite sensitivity to metabolic inhibition resulted in major clinically deleterious interactions. The clinical consequence was an increased risk for the fatal cardiac arrhythmia *torsades de pointes* when coadministered with many commonly administered therapeutics, including antibiotics such as erythromycin and consumer products such as grapefruit juice. This set of examples illustrates the importance of an adequate level of premarketing characterization of DDI risks in the context of the NMEs safety profile and therapeutic index.

Although CYP enzyme-based DDIs have received the greatest amount of attention, it should be noted that DDIs at the level of non-CYP enzymes can also be clinically significant. An example of a serious DDI involving inhibition of a non-CYP enzyme that has resulted in fatal outcomes is the case of interactions between the antiviral drug sorivudine and the cytotoxic anticancer agent 5-fluorouracil (5-FU) or 5-FU prodrugs that are metabolized by the enzyme dihydropyrimidine dehydrogenase (DPD). This interaction is explained by mechanism-based inactivation (MBI) of DPD by a metabolite of sorivudine resulting in an essentially irreversible and long-lasting impairment of DPD activity and 5-FU clearance [2–4]. Another example of clinically significant DDIs resulting from inhibition on non-CYP enzymes is the interaction between the xanthine oxidase (XO) inhibitor allopurinol and 6-mercaptopurine (6-MP) or its imidazolyl derivative, azathioprine. Inhibition of XO-mediated metabolism of 6-MP by allopurinol has been shown to result in a fivefold increase in systemic exposure of orally administered 6-MP [5], necessitating a reduction in the dose of 6-MP or azathioprine in patients requiring coadministration with allopurinol [6].

As a consequence of serious medically significant DDI reports, as exemplified by the above discussed examples, risk assessment and clinical management of DDIs has gained importance across the sectors of medical practice, pharmaceutical research and development, and drug regulation. This is especially important considering the increase in pharmacotherapy options for patients and the emergence of polypharmacy, especially in certain therapeutic areas such as oncology, HIV medicine, and in the geriatric population [7]. Finally, the identification of clinically important interactions with food

products such as grapefruit juice, and importantly herbal products, is also a serious issue. This is partly because they are unfortunately often perceived as innocuous substances without risks. These factors have highlighted DDI awareness and magnified its importance as a public health issue [1,8]. In the face of these drivers of awareness and recognition of the importance of DDIs, there have been significant scientific advances over the last two decades, resulting in critical enablers that now permit a rational and mechanistic approach to drug interaction risk assessment and clinical pharmacologic evaluation. These enablers include: (i) biological and chemical reagents and *in vitro* technology platforms to study drug metabolism and DDIs, made possible by molecular cloning of the human drug-metabolizing enzymes and transporters; and (ii) advances in the science of quantitative *in vitro*–*in vivo* extrapolation (IVIVE) through modeling and simulation to forecast clinical pharmacologic correlates and optimize designs of clinical DDI studies from the results of nonclinical studies. Finally and importantly, advances in quantitative clinical pharmacology have enabled exposure–response understanding of the efficacy and safety profiles of drug candidates during the course of their clinical development. Such exposure–response characterization is necessary for the quantitative and objective estimation of therapeutic index, which is critically important to assess the clinical significance of drug interactions and contribute to prescribing guidance [1].

3.3 FRAMEWORK FOR DDI RISK ASSESSMENT AND EVALUATION IN DRUG DEVELOPMENT

A simple conceptual framework for DDI risk assessment and clinical evaluation in drug development is illustrated in Fig. 3.1. For representative purposes, interactions affecting clearance processes are illustrated in this figure, although this framework is equally applicable for interactions resulting from modulation of drug absorption. As shown in this framework, there are two broad categories of DDIs that require consideration as part of drug development. First, it is important to assess the risk for clinically meaningful alterations in exposure of an NME when it is coadministered with other (marketed) agents that may alter its PK (i.e., NME as the *substrate* drug and the *object* or *victim* of the interaction). A second assessment is of the risk for the NME to produce clinically significant alterations in the PK of concomitant agents, especially those with a narrow therapeutic range (i.e., NME as the *precipitant* or *perpetrator* agent because of its ability to act as a clinically meaningful *inhibitor* or *inducer*). The following sections of this chapter discuss the scientific considerations, experimental methodologies, and strategies employed in answering each of these questions and ultimately integrating the knowledge gained from these assessments into the overall clinical pharmacologic characterization of an NME to inform prescribing guidance. While the focus of this chapter is on metabolic DDIs, it is important to note that transporter-mediated DDIs also represent an important emerging area, and there have been many recent examples of clinically important interactions resulting from modulation of absorption as well as clearance processes via effects of coadministered agents on drug transporter expression and/or activity. A detailed discussion of experimental approaches and strategies for transporter-based DDI risk assessment, and their clinical evaluation is not within the scope of this chapter and the reader is referred to a recent review for current opinion on this topic [9]. Finally, although the focus of this chapter is on DDI risk assessment

Figure 3.1 Conceptual framework for DDI Risk assessment and evaluation in drug development, considering the NME as both the victim or object drug and as the perpetrator or precipitant drug.

and evaluation for small molecule drugs, it should be noted that the topic of PK DDIs with biotherapeutics (e.g., therapeutic antibodies) is an emerging area of science. There have been many recent reports of DDIs between therapeutic antibodies and small molecules resulting, for instance, from indirect immunomodulatory mechanisms that can alter the expression and activity of drug-metabolizing enzymes. For an overview of this emerging area and current expert opinion, the reader is referred to recent review articles [10–13].

3.4 NME AS PRECIPITANT: DDI RISK ASSESSMENT FOR CYP INHIBITION

The assessment of CYP-inhibitory DDI potential of an NME in drug development is a two-step process: (i) *In vitro* estimation of inhibitory potency; and (ii) Translation of *in vitro* inhibitory potency to project potential clinical pharmacologic correlates (i.e., drug interaction magnitude).

3.4.1 *In vitro* CYP inhibition Studies

The *in vitro* experimental models, methodology, and associated data analytic methods for the assessment of the potential for an NME to produce inhibition of the activity of the major drug-metabolizing human CYP isoforms have been developed and refined over the last two decades and are now well established to permit their routine integration into drug discovery and development [14–19]. The most commonly applied approach involves measuring the effect of increasing concentrations of the NME on the metabolic rate in pooled human liver microsomes, of selective index reactions that are

representative of the activities of individual drug-metabolizing CYP isoforms, to estimate IC_{50} values as measures of inhibitory potency. Clinically important CYP isoforms from the standpoint of human drug metabolism and DDIs include CYPs 1A2, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, and 3A4/5 (referred to as 3A). Examples of commonly utilized index reactions for each of these enzymes have been published [15,16,19]. These studies are typically conducted at a substrate concentration equal to the K_m of the index reaction, such that the apparent K_i can be approximated as $0.5 \times IC_{50}$ under the conservative assumption of competitive inhibition. For enzymes that are inhibited sufficiently to enable IC_{50} estimation, a more complete enzyme-kinetic analysis of inhibitory mechanism for definitive estimation of the apparent K_i can be performed following the IC_{50} analysis. Such an experiment will provide definitive information on the kinetic mechanism of inhibition and the associated inhibition constant [20], thereby minimizing the impact of assuming competitive inhibition in subsequent *IVIVE* of clinical interaction magnitude. Such additional refinement, while useful, especially when the underlying mechanism of inhibition is atypical/complex [21], may not be a critical requirement from a pragmatic standpoint for meeting the overall strategic goal of DDI risk assessment in drug development, as estimates of K_i from IC_{50} appear to be sufficiently informative in assessing the risk for PK DDIs and in guiding development of the optimal clinical DDI evaluation strategy [22,23].

An important consideration in the design of *in vitro* CYP inhibition DDI studies is the use of experimental conditions to minimize the extent of nonspecific microsomal binding of the NME. Originally identified as an important factor that can influence estimation of *in vitro* K_m values and thereby confound the accuracy of *in vitro*–*in vivo* scaling of drug clearance [24–27], nonspecific microsomal binding has been established as a source of overestimation of IC_{50}/K_i estimates (i.e., underestimation of inhibitory potency) in CYP inhibition studies [20,28–30]. With the use of sensitive LC/MS/MS bioanalytical methods, it is possible to keep the human liver microsomal protein concentrations to <0.2 mg/mL [19,22] such that the extent of microsomal binding would likely be minimized for most NMEs [e.g., microsomal unbound fraction ($f_{u,mic}$) ≥ 0.8]. If this is not feasible or when dealing with NMEs that are expected to be meaningfully bound even at low microsomal concentrations based on their physicochemical properties (e.g., highly lipophilic bases) or other available data, it would be important to account for this phenomenon and apply necessary corrections for microsomal unbound fraction in the calculation of the unbound inhibitory potency (e.g., $K_{i,u} = f_{u,mic} \times \text{observed } K_i$). Of note, the importance of considering microsomal binding in the calculation of K_i values for basic drugs is recognized in the European Medicines Agency (EMA) draft guideline [31]. This is best done via *in vitro* measurement of the unbound fraction of the NME at the microsomal concentration employed in the CYP inhibition studies [20,28,29]. Alternatively, initial estimates of $f_{u,mic}$ can be calculated from physicochemical properties of the NME using *in silico* models, which have undergone considerable refinement with improvement in their predictive accuracy in recent years [32–34] in relation to the first described model [35]. For highly lipophilic drugs (e.g., $\log P/D > 3$), uncertainty in estimating $f_{u,mic}$ is still high enough that it is advisable to directly measure this parameter for such NMEs [33].

Pooled human liver microsomes represent the most commonly used and generally preferred *in vitro* system for the conduct of CYP inhibition studies. However, it should be noted that CYP inhibition studies can also be performed using human hepatocytes, and there are certain situations where such evaluations may be helpful,

as is discussed later in the section on “mechanism-based inactivation” (Section 3.5). Specifically, when extensive non-CYP-mediated and/or nonmicrosomal metabolism of the NME is expected or known, use of hepatocytes for estimating inhibitory potency for CYP inhibition by the NME may need to be considered as it is possible that there could be *in vitro* system-dependent differences in outcomes, with the outcomes in hepatocytes rather than human liver microsomes being more representative of the clinical outcomes [36].

3.4.2 DDI Risk Assessment from *in vitro* CYP Inhibition Data

Following estimation of inhibitory potency (K_i or IC_{50}), the next step is to put these *in vitro* data in context of the exposures/PK properties of the NME at the clinical dose(s) to forecast the level of risk for DDI with substrates of the enzyme being inhibited, to enable development of risk management plans in later phases of clinical drug development and to guide the strategy/design of clinical DDI studies. Ideally, the objective of IVIVE is to permit prediction of the magnitude of increase in exposure of a coadministered object drug and where possible, a more specific prediction of the nature of the altered plasma concentration–time profile and associated population variability. Substantial progress has been made in the IVIVE of CYP-inhibitory DDI over the last decade, with some recently published examples of successful retrospective predictions from large databases [20,22,37,38]. However, uncertainty still remains in certain key parameters that are critical to the prediction of DDI magnitude (e.g., PK metric that is best suited to serve as a surrogate of enzyme-available inhibitor concentration), as will be reviewed later. Therefore, the quantitative prediction of CYP-inhibitory DDI in drug development remains an emerging area of science without a clear consensus on the best approach that balances scientific rigor and an adequately conservative predictive performance. The approach currently recommended by the FDA Draft DDI Guidance [39], consistent with leading scientific opinion on the topic [14], involves a simple and empirical, yet useful approach intended to provide a conservative categorization of the level of risk based on the $[I]:K_i$ ratio, where $[I]$ is the total systemic maximum plasma concentration of the NME achieved following administration at the highest clinical dose/frequency (e.g., steady-state C_{max}). The underlying scientific rationale for this risk level classification approach is based on the hyperbolic relationship (Fig. 3.2) between $[I]:K_i$ and fold increase in AUC of an orally administered substrate drug whose clearance is entirely mediated 100% via metabolism by the enzyme that is inhibited by the NME—assumptions that intentionally err on the conservative side to project the maximum possible magnitude of a DDI (Eq. 3.1).

$$\frac{AUC_{inhibited}}{AUC_{control}} = \frac{CL_{int,control}}{CL_{int,inhibited}} = 1 + \frac{[I]}{K_i} \quad (3.1)$$

The $[I]:K_i$ ratio cut-offs of <0.1 (corresponding projected maximum increase in AUC of <1.1 -fold) and >1 (corresponding projected maximum increase in AUC of greater than twofold) are to be used for qualitative risk level classification as “low” and “high,” respectively, and are not intended to serve as quantitative predictions of DDI magnitude. The application of this classification is simply to eliminate the need for unnecessary follow-up clinical DDI studies for enzymes that are inhibited with an inferred low DDI risk, and to sequentially prioritize the conduct of clinical DDI studies

Figure 3.2 Relationship between the $I:K_i$ ratio for CYP inhibition by an NME and the associated level of DDI risk assessed based on the maximum expected fold increase in systemic exposure of an orally administered object drug whose oral clearance is mediated solely by hepatic metabolism by the inhibited enzyme.

for enzymes that are inhibited with decreasing levels of DDI risk, as will be discussed later. Consider, for example, the anticancer drug everolimus, an mTOR (mammalian target of rapamycin) inhibitor, indicated for the treatment of advanced renal cell carcinoma. Everolimus inhibits CYP2D6 activity *in vitro*; however, the clinically observed mean steady-state $C_{\max}$ at the recommended 10 mg daily dose is more than 12-fold below the CYP2D6 inhibitory K_i , based on which the everolimus USPI concludes that an effect of everolimus on the metabolism of CYP2D6 substrates is unlikely [40]. This example illustrates how *in vitro* data, when clearly indicative of low DDI risk, can inform prescribing guidance without the need for unnecessary clinical DDI studies.

The approach to DDI risk assessment using the $[I]:K_i$ ratio alone (with $[I]$ defined as the clinically observed systemic $C_{\max}$ of the NME), while simple and pragmatically straightforward, is not without limitations. The assumptions underlying this simple classification system have been addressed in multiple quantitative enrichments to the framework that have built in considerations of the appropriate metric of $[I]$, route of administration of the victim drug, and potential for extrahepatic metabolism. Finally, if the goal is to make quantitative predictions of DDI magnitude that extend beyond risk

level categorization, it is important to consider the fraction of victim drug clearance that is mediated by metabolism via the inhibited enzyme ($f_{m(CYPi)}$). Each of these aspects is reviewed briefly in the following subsections.

3.4.3 Considerations in Defining [I]

A key consideration in DDI risk assessment from *in vitro* enzyme inhibitory potency is the selection of the best PK surrogate of the enzyme-available inhibitor concentration in the liver. The selection of an appropriate surrogate for [I] has been an extensively debated topic for nearly two decades, with multiple reports of variable predictive success resulting from use of various surrogates—some more scientifically valid and appealing than others. Considering that this continues to be an emerging area of science without global regulatory consensus guidelines available at the time of writing of this chapter, this chapter does not provide any definitive recommendations on the preferred approach to estimate [I] for DDI predictions in drug development but will only discuss the relative merits and limitations of the available approaches. For metabolism by liver microsomal enzymes, enzyme-available inhibitor concentration in the hepatocyte should in principle equal the unbound concentration in hepatic cytosol around the enzyme, which is unfortunately impossible to directly measure in humans. Pharmacologic principles and specifically the unbound drug hypothesis would suggest that the unbound plasma concentration of the inhibitor would be expected to be in equilibrium with the unbound concentration within the hepatocyte (in the absence of active hepatic uptake), suggesting that it may be the most appropriate surrogate for [I]. However, multiple reports have consistently demonstrated that the use of unbound systemic exposure (either steady-state average concentration over the dosing interval or steady-state peak concentration) results in substantial underpredictions of DDI magnitude, with unacceptably high false negative prediction rates, such that major clinically important DDIs would be missed. Multiple reasons can potentially explain the poor performance of unbound systemic exposure as a surrogate for [I]. For orally dosed inhibitors that undergo first-pass hepatic extraction, significant portal/systemic concentration gradients can be expected. Therefore, the unbound hepatic inlet concentration has been proposed as a suitable surrogate for [I] based on the recognition that use of systemic unbound concentrations can underestimate the transiently high concentrations that will be “seen” by the drug-metabolizing enzymes in the liver following an oral dose of the NME, and therefore result in underprediction of DDI magnitude. This can be readily calculated using Equation 3.2 where $I_{\max}$ is the systemic maximum concentration of the inhibitor, f_u is its plasma free fraction, f_a is its fraction absorbed, k_a is its absorption rate constant, and Q_h is hepatic blood flow [41,42].

$$I_{\text{inlet,max,u}} = f_u \times \left(I_{\max} + \frac{f_a \cdot \text{dose} \cdot k_a}{Q_h} \right) \quad (3.2)$$

Another potential reason for underprediction of DDI magnitude with the use of unbound systemic concentrations is the active hepatic uptake of certain inhibitors that can result in unbound hepatocellular concentrations in excess of the corresponding unbound systemic concentrations. Considering these complexities and uncertainties, and in the interest of having a conservative, yet simple approach to DDI risk assessment from *in vitro* CYP-inhibitory potency data, two distinct approaches are currently

advocated by the FDA and the EMA draft DDI guidance documents, respectively. The regulatory draft guidance document from FDA conservatively recommends the use of total systemic $C_{\max}$ of the CYP-inhibitory NME for calculating the $[I]:K_i$ ratio, with a 10-fold safety factor as discussed earlier (i.e., risk for DDI cannot be excluded unless $[I]:K_i$ ratio is <0.1) [39]. The EMA draft guideline that was recently released for comment considers plasma protein binding and recommends unbound systemic $C_{\max}$ as the surrogate of $[I]$ but accordingly recommends the use of higher safety factors to account for factors such as portal/systemic concentration gradients and uncertainties in K_i estimation, and thereby minimize false negative risk assessments. A 50-fold safety factor is recommended (i.e., risk for DDI cannot be excluded unless $[I]:K_i$ ratio is $\leq 1/50$), with a higher safety factor of 250-fold (i.e., risk for DDI cannot be excluded unless $[I]:K_i$ ratio is $\leq 1/250$) for drugs with $>99\%$ plasma protein binding [31]. In addition to consideration of the systemic unbound exposure of the inhibitor, the EMA draft guideline also recommends consideration of intestinal exposure when the enzyme being inhibited is known to have pronounced intestinal expression (e.g., CYP3A). Two measures of intestinal exposure are recommended to be calculated: a maximum luminal concentration calculated as the maximum dose taken at one occasion divided by 250 mL and a predicted maximum concentration in the enterocyte using Equation 3.3 [43], where Q_{ent} is the enterocytic blood flow (~ 248 mL/min):

$$I_{\text{gut}} = \frac{f_a \times \text{Dose} \times k_a}{Q_{\text{ent}}} \quad (3.3)$$

Safety factors of 10-fold (for the calculated maximum luminal concentration) and 50-fold (for the calculated concentration in the enterocyte) are recommended to be jointly applied (in addition to the previously discussed approach to risk assessment based on the systemic unbound $C_{\max}$) for translational assessment of clinical DDI risk from *in vitro* CYP-inhibitory potency data [31]. The performance characteristics of these suggested safety factors remain to be investigated.

3.4.4 Quantitative Predictions of DDI Magnitude: Victim Drug-Specific Considerations

An important factor that determines the magnitude of a DDI is not only the potency of inhibition of the drug-metabolizing enzyme by the NME and the NME's exposure at clinical dose(s) but also the fraction of total clearance of the object drug that is mediated by metabolism via the specific inhibited enzyme (Eq. 3.4; Fig. 3.3), denoted variably by f_m , $f_{m(\text{CYP})}$, $f_{m(\text{CYPi})}$, or the contribution ratio (CR) in previous investigations of CYP-based DDIs [22,23,44–48].

$$\frac{\text{AUC}_{\text{inhibited}}}{\text{AUC}_{\text{control}}} = \frac{1}{(1 - f_{m(\text{CYPi})}) + \frac{f_{m(\text{CYPi})}}{(1 + \frac{I}{K_i})}} \quad (3.4)$$

The approach to DDI risk assessment based solely on $I:K_i$ ratio (Fig. 3.2) conservatively assumes that $f_{m(\text{CYPi})}$ of the object drug is unity, although this is seldom the case even for highly selective probe substrates of the major human CYP enzymes, with estimated values of $f_{m(\text{CYP1A2})}$ of ~ 0.95 for caffeine, $f_{m(\text{CYP2C9})}$ of ~ 0.91 for *S*-warfarin, $f_{m(\text{CYP2C19})}$ of ~ 0.87 for omeprazole, $f_{m(\text{CYP2D6})}$ of ~ 0.9 for desipramine,

Figure 3.3 Fraction of total clearance of the object drug that is mediated by metabolism via the specific inhibited enzyme ($f_{m(CYP_i)}$) and the precipitant's I:K_i ratio as determinants of clinical DDI magnitude.

and $f_{m(CYP3A)}$ of ~ 0.93 for midazolam, as reviewed previously [49]. Considering the nonlinear relationship between $f_{m(CYP_i)}$ of the object drug and predicted interaction magnitude for a given I:K_i ratio (Fig. 3.3), sensitivity of the IVIVE of DDI to the assumption of $f_{m(CYP_i)}$ of unity can be quite large and result in a substantial overprediction of DDI magnitude, even when dealing with a highly selective substrate with $f_{m(CYP_i)} \geq 0.9$. Accurately defining $f_{m(CYP_i)}$ of the object drug with a high level of precision (e.g., 0.85 vs 0.95) is not straightforward. One approach involves the derivation of $f_{m(CYP_i)}$ from the results of clinical DDI studies with a strong and selective inhibitor (e.g., ketoconazole for CYP3A), and has been utilized for estimating $f_{m(CYP3A)}$ of midazolam and other CYP3A substrates [22,48]. It is important to note that the assumption of complete and specific inhibition of the target enzyme by a strong inhibitor is inherent to such an approach. The adequacy of this assumption of complete inhibition of the target enzyme depends on the potency of the inhibitor in relation to time course of inhibitor concentrations achieved in the DDI study and the mechanism of inhibition (reversible vs mechanism based). Another approach that is probably scientifically most appealing (provided all necessary data are available to enable its application) involves a calculation of $f_{m(CYP_i)}$ from various sources of data, including a quantitative knowledge of the clearance mechanisms of the object drug (e.g., as gained from the results of a radiolabeled mass balance study with adequate quantitative tracking of the chemical fate of the object drug in excreta) and quantitative *in vitro* reaction phenotyping of its biotransformation pathways. This approach has been used successfully in estimating $f_{m(CYP1A2)}$ of theophylline and clozapine [22,49]. With this approach, it is important to note that although the identification of major versus minor contributing enzymes can be expected to be consistent between the complementary approaches of *in vitro* reaction phenotyping, quantitatively equivalent estimates of relative contributions of each enzyme are not always obtained, introducing uncertainty in the derived $f_{m(CYP_i)}$.

Finally, the most straightforward approach is in the setting where the target enzyme is polymorphically expressed and clinical PK data are available in extensive metabolizer (EM) and poor metabolizer (PM) populations. In such cases, $f_{m(\text{CYPi})}$ can be readily estimated as one minus the inverse of the ratio of exposure of the object drug following oral dosing in PM versus EM subjects. Such an approach has been used successfully in estimating the $f_{m(\text{CYPi})}$ of commonly used probe substrates of CYP2C9, CYP2C19, and CYP2D6 [22,45,49]. While the certainty in estimation of $f_{m(\text{CYPi})}$ can be considered to be high in these cases when EM/PM PK data are available, the same is not true when dealing with the other methods of estimating this input parameter, where the associated uncertainty is relatively greater. The topic of defining $f_{m(\text{CYPi})}$ is discussed further in a later section in the context of risk assessment for DDI with the NME as the object drug, but the principles are equally applicable to defining this critical parameter of the object drug to enable quantitative predictions of the magnitude of CYP-inhibitory DDI produced by an NME as the precipitant.

3.4.5 Quantitative Predictions of DDI Magnitude: NME-Specific Considerations

When using Equation 3.4 to make quantitative predictions of DDI magnitude, a key question as discussed earlier for qualitative (categorical) risk assessment is the selection of PK surrogate for [I] of the NME inhibitor. Various measures of [I] (e.g., total systemic $C_{\max}$, unbound systemic $C_{\max}$, total maximum hepatic inlet concentration, and unbound maximum hepatic inlet concentration) have been investigated in prospective and retrospective exercises of IVIVE of CYP-inhibitory DDI without general consensus on the surrogate for [I] associated with best predictive performance. In a large retrospective analysis based on a primary database of *in vitro* CYP-inhibitory potencies by Obach and colleagues [22], use of unbound maximum hepatic inlet concentration (Eq. 3.2) provided the best predictive accuracy relative to other metrics of [I], including total systemic $C_{\max}$, unbound systemic $C_{\max}$, and total maximum hepatic inlet concentration. In contrast to these observations, use of the unbound maximum hepatic inlet concentration of the inhibitor resulted in an overall underprediction of DDI magnitude in another retrospective analysis by Brown and colleagues [20], also based on a primary database of *in vitro* CYP-inhibitory potencies. This latter study found total systemic average concentration to be associated with the best predictive accuracy (91% of predictions within twofold of the observed DDI magnitude), which is unfortunately at odds with expectations from the unbound drug hypothesis and is therefore harder to explain from a mechanistic standpoint. The case of inhibition of CYP2C8 by the leukotriene receptor antagonist montelukast represents an example that supports the importance of considering plasma protein binding of the inhibitor during IVIVE of DDI magnitude. Montelukast has been identified to be a potent CYP2C8 inhibitor with a K_i of ~ 9 nM [30]. Total systemic plasma concentrations of montelukast at the 10 mg/day therapeutic dosing regimen (steady-state average concentration of ~ 0.4 μM ; steady-state $C_{\max}$ of ~ 0.9 μM) are in far excess of the *in vitro* K_i for CYP2C8 inhibition, such that nearly complete inhibition of CYP2C8 should be anticipated. However, clinical DDI studies with CYP2C8 substrates such as repaglinide [50] and pioglitazone [51] have consistently demonstrated that montelukast does not alter the PK of these agents, confirming the lack of CYP2C8 inhibition by montelukast *in vivo*. Montelukast is highly plasma protein bound ($>99\%$) and the estimated unbound hepatic inlet $C_{\max}$ calculated using Equation 3.2 is <11 nM, translating to a <2.2 -fold DDI magnitude even if

100% of clearance of the substrate drug is via CYP2C8-mediated metabolism [30]. As plasma protein binding of montelukast is not precisely known and exact estimates of $f_{m(\text{CYP2C8})}$ of rosiglitazone, pioglitazone, and repaglinide are difficult to obtain considering involvement of nonmetabolic OATP1B1 transporter-mediated clearance of these agents, it is difficult to more precisely predict the quantitative extent of DDIs with montelukast. Nevertheless, it is clear that predictions that do not consider the plasma protein binding of montelukast would substantially overpredict the risk for clinical DDIs with CYP2C8 substrates.

For CYP3A substrates administered orally, the quantitative prediction of DDI magnitude following administration of a CYP3A inhibitor should consider inhibition of intestinal metabolism in addition to hepatic metabolism of the object drug, due to the established expression of CYP3A in the small intestine and clinically important contribution to the clearance of many (but not all) substrates. The previously discussed IVIVE analysis by Obach and colleagues [22], accounted for inhibition of intestinal first-pass metabolism for CYP3A inhibitory DDIs, based on inclusion of the fold increase in the intestinal bioavailability as a multiplicative term together with the hepatic component. This is implemented using Equation 3.5 [52], where F_G is the baseline value of intestinal bioavailability of the object drug, I_g is the estimated intestinal concentration of the inhibitor (calculated using Eq. 3.3).

$$\frac{\text{AUC}_{\text{inhibited}}}{\text{AUC}_{\text{control}}} = \frac{1}{F_G + \frac{(1-F_G)}{\left(1 + \frac{I_g}{K_i}\right)}} \times \frac{1}{(1 - f_{m(\text{CYPi})}) + \frac{f_{m(\text{CYPi})}}{\left(1 + \frac{I}{K_i}\right)}} \quad (3.5)$$

The contribution of CYP3A inhibition in the intestine to the overall magnitude of a DDI clearly depends on the baseline F_G of the object drug. For highly potent inhibitors, the $I_g : K_i$ ratio may be large enough such that the first term in Equation 3.5 can be approximated as the inverse of baseline F_G , as has been done in the above discussed analysis by Brown and colleagues [20] for the CYP3A-inhibitory azole antifungal agents. For a detailed review of the assumptions and considerations associated with IVIVE of intestinal inhibition in the overall prediction of DDI magnitude, the reader is referred to a recent comprehensive review on this topic [53].

3.5 NME AS PRECIPITANT: MECHANISM-BASED CYP INACTIVATION DDI

Many clinically important PK DDIs result from impairment of metabolic clearance via MBI of CYP enzymes. This can be readily appreciated from an examination of the strong and moderate inhibitors of the major human drug-metabolizing enzyme CYP3A identified in the 2006 FDA draft guidance on drug interaction studies [39]. Fourteen out of 19 identified clinically significant CYP3A inhibitors are either established or putative mechanism-based inactivators of the enzyme, ranging from the natural product grapefruit juice to prescription drugs spanning several therapeutic classes, including antiretroviral agents (e.g., ritonavir, saquinavir), antibiotics widely used in general practice (e.g., clarithromycin, erythromycin), the calcium channel blockers diltiazem and verapamil, and the antidepressant agent nefazodone.

3.5.1 *In vitro* Diagnosis of MBI

The *in vitro* CYP inhibition studies and conceptual framework to IVIVE of DDI magnitude discussed in the previous section are only applicable to the setting of reversible CYP inhibition and are not appropriate when the investigational agent is a mechanism-based inactivator of a drug-metabolizing enzyme. Reversible CYP inhibition is only concentration dependent (at a given substrate concentration), whereas MBI is characterized by both concentration *and* time-dependent inactivation of the enzyme, secondary to metabolic activation of the inactivator (often described as a suicide inhibitory mechanism). An efficient approach to diagnosis of MBI by an NME is a test of enhancement of its apparent inhibitory activity following preincubation with human liver microsomes (or specific recombinant CYP isoforms) and NADPH before incubation with the isoform-selective index substrate. If the test compound is a mechanism-based inactivator, the above described preincubation process will result in a leftward shift in the IC_{50} curve (relative to a control experiment conducted alongside with the cofactor NADPH omitted in the preincubation period) and a correspondingly smaller estimate of the IC_{50} [54,55]. For simple reversible inhibitors, the IC_{50} curves will be expected to be essentially indistinguishable when interpreted in context of experimental variability, or may actually demonstrate an apparently greater IC_{50} following preincubation, as a consequence of metabolic consumption of the reversible inhibitor during the preincubation. If the above described diagnostic test is positive indicating time-dependent inhibition, further DDI risk assessment requires a full *in vitro* kinetic analysis to estimate the parameters characterizing MBI by the NME. An abbreviated empirical IVIVE approach using the “shifted IC_{50} ” estimated following preincubation of the inactivator with human liver microsomes and NADPH, in the context of the reversible inhibition model (i.e., using one-half of the “shifted IC_{50} ” in place of K_i in Eq. 3.5) has been explored [55,56]. The “shifted IC_{50} ” is inversely related to the $k_{inact} : K_I$ ratio, which is a measure of the inactivator’s intrinsic efficiency [57,58]. However, the performance of quantitative DDI predictions using the “shifted IC_{50} ” is suboptimal, and it is therefore recommended that the appropriate mechanistic model for IVIVE of MBI based on *in vitro* parameters derived from a full enzyme-kinetic characterization of inactivation be utilized for definitive quantitative predictions and clinical DDI risk assessment [56].

3.5.2 *In vitro* Kinetic Characterization of MBI

The two primary kinetic parameters of relevance to IVIVE of MBI DDI are a capacity term reflecting the maximum rate of loss of enzymatic activity that the inactivator is capable of producing (k_{inact}), and a potency term (K_I) reflecting the concentration of the inactivator at which half-maximal inactivation rate ($0.5 \times k_{inact}$) is achieved. The inactivator at varying concentrations ($[I]$) is preincubated with the source of enzyme (human liver microsomes or recombinant CYP preparation) and NADPH for varying durations of time (t) before dilution into a secondary metabolic incubation (activity assay) containing NADPH and an index substrate of the target CYP isoform at concentrations in excess of its K_m . Dilution following the preincubation and use of saturating substrate concentrations in the activity assay help minimize any surmountable reversible inhibition, which may otherwise potentially confound estimation of the true kinetic parameters of CYP inactivation. The time course of loss of CYP activity over the duration of the preincubation is analyzed to estimate the apparent first-order

inactivation rate constant λ at each concentration of inactivator.

$$\text{Activity} = \text{Activity}_{t=0} \cdot e^{-\lambda t} \quad (3.6)$$

The parameters k_{inact} and K_I characterizing the hyperbolic relationship between λ and $[I]$ are subsequently estimated using either a nonlinear regression approach or the less preferred approach involving linear transformations of the data (e.g. Kitz–Wilson analysis).

$$\lambda = \frac{k_{\text{inact}} \cdot [I]}{[I] + K_I} \quad (3.7)$$

The design of *in vitro* inactivation kinetic studies and subsequent data analysis should be performed in a manner that minimizes bias and increases precision of the estimated parameters [59]. For a detailed review of best practices for the experimental designs and data analytical approaches to *in vitro* studies of CYP inactivation, the reader is referred to a recent review that provides an expert opinion on the topic from a PhRMA perspective [60].

A complete elimination of bias in parameter estimates may be difficult to achieve using conventional experimental and data analytical approaches for inactivation kinetic characterization, as illustrated via theoretical simulations of the fidelity of such traditional approaches [61]. For example, metabolic depletion of the inactivator during the preincubation (as a consequence of which, nominal concentrations may overestimate the actual concentrations during the preincubation) as well as possible inactivation of the enzyme during the metabolic incubation with probe substrate (i.e., inadequate “quenching” of inactivation by dilution when the metabolic incubations with the probe substrate are conducted for relatively long durations) can introduce bias in k_{inact} and K_I estimates. These considerations emphasize the importance of using the lowest required microsomal concentration during the preincubation and the shortest possible duration of incubation for the metabolic activity measurement. Other features of the experimental protocol (e.g., dilution factor employed between the preincubation and incubation steps) can additionally influence the estimated inactivation kinetic parameters as illustrated in a series of studies on CYP2D6 inactivation by 3,4-methylenedioxymethamphetamine [62,63]. To address these issues, Yang and colleagues [64] have proposed a mechanistically based experimental protocol to eliminate the bias introduced in the estimation of inactivation kinetic parameters with the above described conventional approach. This approach involves three separate experiments to assess the metabolism of the inactivator, its ability to cause competitive inhibition, and its ability to cause time-dependent inhibition, followed by a simultaneous analysis of all resulting data to permit a model-based extraction of MBI kinetic parameters [64]. A variation of this approach referred to as *progress curve analysis* has been described and applied to estimate and distinguish the potencies of reversible inhibition and MBI of the CYP1A2 inactivators resveratrol, furafylline, and dihydralazine within the same experiment [65]. The complete time courses of substrate turnover were characterized in the absence of the inactivator and in the presence of varying concentrations of the inactivator. The reversible K_i was estimated based on the concentration–effect relationship for inhibition of initial velocity of substrate metabolism and the inactivation kinetic parameters (K_I and k_{inact}) were estimated based on kinetic analysis of the entire progress curve of substrate turnover

followed by characterization of the concentration–effect relationship for inactivation using the time-averaged inactivator concentration over the duration of the incubation [65]. Additional research is required to fully evaluate the performance characteristics of these novel promising approaches across CYP isoforms and their application for MBI DDI risk assessment.

3.5.3 Considerations in *In vitro* System Selection for MBI Kinetic Studies

In vitro studies of MBI can be performed using recombinantly expressed CYP enzyme isoforms, human liver microsomes, or hepatocytes. It should be noted that MBI kinetic parameters estimated using certain recombinantly expressed CYP preparations may not be reflective of those estimated using native human liver microsomes [66]. Therefore, caution should be exercised in their use for DDI risk assessment, as has been demonstrated for CYP3A inhibitory DDIs produced by macrolide antibiotics [67]. A recent study suggested a better predictive performance of IVIVE based on *in vitro* inactivation kinetic parameters determined in primary human hepatocytes compared to human liver microsomes [68]. Nevertheless, when viewed in the context of multiple reports that suggest reasonably successful classification of the level of DDI risk using time-dependent inhibition studies in human liver microsomes, and the relative convenience and opportunity for “standardization” of this experimental system (e.g., use of pooled human liver microsomes to represent the “population average” distribution of enzymes), the most commonly utilized system for studies of MBI for DDI risk assessment is human liver microsomes. Consistently, human liver microsomes represent the recommended *in vitro* system for estimation of kinetic parameters of inactivation in the expert opinion from the PhRMA [60].

It should, however, be noted that if substantial non-CYP- and/or nonmicrosomal-mediated metabolism of the NME is expected and if such metabolism modifies the inactivation effects of the NME, data from human hepatocytes rather than human liver microsomes may be more translatable to the clinical setting. This has been demonstrated recently for gemfibrozil, bupropion, and ezetimibe [36]. Gemfibrozil produces clinically relevant inhibition of CYP2C8 through MBI of the enzyme by its acyl glucuronide. Bupropion produces clinically relevant inhibition of CYP2D6 through metabolism-dependent inhibition of the enzyme by its reduced metabolites *erythro*- and *threo*-hydrobupropion. As hepatocytes represent a more complete biotransformation system compared to human liver microsomes, potent inhibition of CYP2C8 and CYP2D6 by gemfibrozil and bupropion, respectively, are readily observed following preincubation of hepatocytes with these drugs but are not observed using human liver microsomes as the *in vitro* system, where direct evaluation of the metabolites is necessary to observe potent enzyme inhibition [36]. The reverse is true in the case of ezetimibe, where potent MBI of CYP3A4 is observed in human liver microsomes, whereas this is not the case when using hepatocytes as the *in vitro* system, because of turnover of ezetimibe by direct glucuronidation, which occurs *in vivo*, resulting in the lack of clinically relevant CYP3A inhibition [36].

Considering the relatively large microsomal concentrations generally used in the preincubation step in *in vitro* kinetic studies of MBI, nonspecific microsomal binding can be significant, introducing bias in K_I estimates, jeopardizing their applicability in subsequent IVIVE of DDI magnitude. Therefore, correction of apparent K_I estimates for microsomal binding can be important in getting unbiased estimates of inactivator

potency for highly lipophilic basic inactivators that can be substantially bound to microsomal phospholipids. For example, failure to consider nonspecific microsomal binding of paroxetine results in a greater than threefold underprediction of the magnitude of interactions with CYP2D6 substrates [69].

3.5.4 DDI Risk Assessment and IVIVE for MBI

The theoretical framework that guides IVIVE of DDI magnitude resulting from CYP inactivation was first described by Hall and colleagues in 2000 [70]. As with IVIVE of reversible inhibition, the first step in IVIVE of MBI is to estimate the effect of the inactivator on intrinsic clearance of metabolism via the inactivated enzyme. Considering that steady-state levels of CYP enzymes *in vivo* are maintained by a balance of zero-order production (k_{syn}) and first-order degradation (rate constant, k_{deg}), the perturbation of this system by an inactivator (i.e., introduction of an additional mechanism of loss of active enzyme characterized by the apparent first-order rate constant λ) without an effect on enzyme synthesis rate would be expected to result in the following derivation of the expression for fold reduction in intrinsic clearance:

$$\frac{CL_{int, control}}{CL_{int, I}} = \frac{E_{ss}}{E_{ss, I}} = \frac{k_{syn}/k_{deg}}{k_{syn}/k_{deg} + \lambda} = \frac{k_{deg} + \lambda}{k_{deg}} = \frac{k_{deg} + \frac{[I] \cdot k_{inact}}{[I] + K_I}}{k_{deg}} \quad (3.8)$$

The model described above provides the fundamental basis of IVIVE of MBI DDI and is shown in Fig. 3.4. The 2010 EMA draft guideline on DDIs recommends use of the derived expression in Equation 3.8 to predict the effect of NMEs that display time-dependent inhibition *in vitro* on intrinsic clearance of the enzyme being inactivated. If $\geq 30\%$ inhibition is predicted using this equation (with the estimates of $[I]$ and safety factors recommended in the guideline as discussed previously for reversible inhibition), *in vivo* inhibition may not be excluded and a clinical DDI study is recommended [31].

Figure 3.4 Schematic illustration of the enzyme-kinetic mechanistic model underlying mechanism-based inactivation.

Figure 3.5 (a) MBI surface plot showing the fold reduction in intrinsic clearance as a function of $I:K_I$ and $k_{\text{inact}} : k_{\text{deg}}$. (b) Contour map positioning as a tool for DDI risk assessment via MBI. See text for details.

Rearranging the terms in the derived expression in Equation 3.8, a modified form of this expression can be obtained and is shown in Equation 3.9 [71].

$$\frac{CL_{\text{int,control}}}{CL_{\text{int,I}}} = 1 + \frac{\left(\frac{k_{\text{inact}}}{k_{\text{deg}}}\right)}{1 + \frac{1}{\left(\frac{I}{K_I}\right)}} \quad (3.9)$$

It follows from Equation 3.9 that the fold decrease in intrinsic clearance of metabolism via the enzyme being inactivated is a complex nonlinear function of $I:K_I$ and $k_{\text{inact}} : k_{\text{deg}}$ (Fig. 3.5a) and that various combinations of $I:K_I$ and $k_{\text{inact}} : k_{\text{deg}}$ can result in identical fold reductions in intrinsic clearance. MBI interaction contour maps can thus be generated to serve as a visual aid to guide risk assessment for DDI from *in vitro* inactivation kinetics, initial estimates of k_{deg} , and of enzyme-available inactivator concentration *in vivo*. Each contour is a slice of the surface at a given magnitude of fold decrease in intrinsic clearance of the enzyme, and tracks combinations of $I:K_I$ and $k_{\text{inact}} : k_{\text{deg}}$ producing identical fold reductions in intrinsic clearance (Fig. 3.5b). Therefore, rank ordering of the level of DDI risk associated with individual compounds within or across chemical series can be readily done based on the interaction contour on which they fall (or are closest to), which may not be readily apparent based on inspection of the four independent input parameters (k_{inact} , K_I , k_{deg} , $[I]$). This is illustrated in Fig. 3.5b where three hypothetical compounds characterized as inactivators (X with $I:K_I$ of 0.02 and $k_{\text{inact}} : k_{\text{deg}}$ of 1000; Y with $I:K_I$ of 2 and $k_{\text{inact}} : k_{\text{deg}}$ of 40; and Z with $I:K_I$ of 0.02 and $k_{\text{inact}} : k_{\text{deg}}$ of 40) are compared on a MBI contour map. Despite vastly different values of $I:K_I$ and $k_{\text{inact}} : k_{\text{deg}}$, the level of DDI risk associated with X and Y can be inferred to be comparable because they both fall close to the same contour (tracking an ~25-fold reduction in intrinsic clearance), albeit at different positions as dictated by their relative potencies and rates of inactivation. In contrast, compound Z represents a significant improvement over X or Y with respect to risk for MBI DDI, as is evident from its position on a contour

tracking a less than twofold reduction in intrinsic clearance. An important lesson learned from examination of compound X is that despite a very small $I:K_I$ ratio of 0.02 (which would typically be considered to be associated with negligible risk and a remote possibility of a clinically meaningful interaction if the inhibition mechanism were reversible), the resulting fold reduction in intrinsic clearance is predicted to be very large (~ 20 -fold), as a consequence of very rapid inactivation that is three orders of magnitude faster than the rate of degradation of the inactivated CYP isoform. This emphasizes the importance of not only potency considerations but also rate considerations when making inferences regarding the level of DDI risk associated with MBI. Making comparisons of K_I against clinical exposures of the inactivator is inappropriate for risk assessment unless considered in context of the $k_{\text{inact}} : k_{\text{deg}}$ ratio. Examples include CYP2D6 inactivation by paroxetine, CYP2C19 inactivation by ticlopidine, and CYP3A4/5 inactivation by erythromycin, verapamil, and diltiazem, which are all associated with clinically significant DDIs despite the corresponding $I:K_I$ ratios being below 0.1 [55,71].

For the quantitative prediction of DDI magnitude with CYP inactivators, the fold decrease in intrinsic clearance of the inactivated enzyme (Eq. 3.9) takes the place of the “ $1 + (I/K_I)$ ” term in Equation 3.5, resulting in the following equation (where $k_{\text{deg(intestine)}}$ and $k_{\text{deg(liver)}}$ are the first-order turnover rate constants for the intestinal and hepatic enzyme):

$$\frac{\text{AUC}_{\text{inhibited}}}{\text{AUC}_{\text{control}}} = \frac{1}{F_G + \frac{(1-F_G)}{\left(1 + \frac{\left(\frac{k_{\text{inact}}}{k_{\text{deg(intestine)}}}\right)}{1 + \frac{1}{\left(\frac{I}{K_I}\right)}}\right)}}} \times \frac{1}{(1 - f_m(\text{CYPi})) + \frac{f_m(\text{CYPi})}{\left(1 + \frac{\left(\frac{k_{\text{inact}}}{k_{\text{deg(liver)}}}\right)}{1 + \frac{1}{\left(\frac{I}{K_I}\right)}}\right)}}} \quad (3.10)$$

Use of this equation has resulted in reasonable predictions of the magnitude of DDIs produced by CYP inactivators based on retrospective analyses from primary *in vitro* databases that suggest that unbound systemic exposure appears to be the best surrogate for hepatic [I], with the use of Equation 3.3 for estimation of intestinal [I] [55,56].

3.5.5 CYP Turnover Half-Life: A key parameter for IVIVE of MBI DDI

It is readily apparent on inspection of Equations 3.8–3.10 that a key drug-independent physiological parameter that is necessary to translate *in vitro* data on CYP inactivation to predict clinical pharmacologic consequences is the degradation/turnover rate constant (k_{deg}) of the enzyme *in vivo*. While relatively good estimates of *in vivo* k_{deg} are available for certain human CYP enzymes (e.g., hepatic CYPs 1A2, 2C8, 2D6, 2E1, and intestinal CYP3A), the same is not true for other enzymes where *in vivo* estimates are either lacking (e.g., CYP2C9, CYP2C19) or are available with a high degree of uncertainty reflected by a wide range of estimates across literature reports that have estimated this parameter using complementary methods and data analytic approaches with varying associated assumptions (e.g., hepatic CYP3A4). A detailed review of the methods used to estimate k_{deg} , their merits and limitations, and a critical analysis of available data in this regard is outside the scope of this chapter and the reader is referred to a recent detailed overview [72]. For CYP1A2, a half-life of 39 h is estimated

based on time course of deinduction on smoking cessation [73]. For CYP2D6, a half-life of 51 h has been derived by noncompartmental deconvolution of the steady-state serum half-life of paroxetine from the time course of recovery of CYP2D6 activity following cessation of treatment with the inactivator [69,74]. In the case of CYP2E1, the time course of both deinduction (during the withdrawal phase in alcoholics) and recovery following disulfiram inactivation have been characterized and both estimates yield comparable CYP2E1 turnover half-lives of 60 h [75] and 51 h [76], respectively. A recent report estimated the half-life of hepatic CYP2C8 to be 22 h based on analysis of the time course of recovery of repaglinide oral clearance following inactivation by gemfibrozil [77]. The turnover half-life of intestinal CYP3A (likely reflective of the kinetics of enterocyte turnover in the intestinal epithelium) has been estimated as 23 h based on the time course of recovery following inactivation by grapefruit juice ingestion [78]. For hepatic CYP3A, a wide range of estimates (24–140 h) is available based on analysis of clinical data of the time course of induction or deinduction, or of recovery from inactivation using CYP3A substrates of varying specificity and different methods of data analysis ranging from nonlinear regression of time course of induction/deinduction [72,79] to more sophisticated analyses using mechanistic population PK models describing autoinduction [80]. CYP3A turnover half-lives of 28 h [81,82], 36 h [37,55,71,83], 48 h [68], and 72 h [56,84] have been used in previous analyses of IVIVE of MBI DDI. Considering the uncertainty in half-life of certain human CYP enzymes and hepatic CYP3A, in particular, a useful approach to IVIVE of CYP3A MBI is to select a certain reasonable initial estimate (within the 24–72 h range, for instance) and then examine the sensitivity of the predicted drug interaction magnitudes around this value. The key question is whether the prediction for a given inactivator using the initial estimate of k_{deg} falls on the dynamic range of the sensitivity curve or on a relatively flat portion of the curve, as this would translate to a relatively low versus high confidence in prediction, respectively. The previously discussed MBI contour mapping approach can be useful in visually interpreting the results of analyses of sensitivity of the outcome of IVIVE of MBI DDI to uncertainty in k_{deg} when reliable estimates of this parameter are not available [49].

3.6 NME AS PRECIPITANT: CYP INDUCTION DDI

Induction of drug-metabolizing enzymes is an important mechanism of clinically significant DDIs. Increases in enzyme content secondary to either increased expression or protein stabilization by an NME can result in an increase in intrinsic clearance of metabolism by the induced enzyme, leading to decreased systemic exposure of coadministered drugs that are substrates for the enzyme that is induced. Although this typically manifests itself as a reduction in therapeutic efficacy (e.g., loss of oral contraceptive efficacy due to decreased exposure by enzyme-inducing antiepileptic drugs) and increased dosage requirements (e.g., higher cyclosporine A dose requirement in patients taking St. John's wort) in the setting of induction, increases in metabolism can also result in an alteration of the safety profile when dealing with drugs with active and/or toxic metabolites. Unlike reversible inhibition, induction DDIs are time dependent in their onset and offset, complicating their clinical management both after initiation of treatment with an inducer and in the deinduction period following cessation of treatment with the inducer.

3.6.1 Molecular Mechanisms of Induction and *In vitro* Assay Platforms

The major mechanism of induction of drug clearance is via increased expression of drug-metabolizing enzymes and transport proteins by the inducer via increased transcription. Therefore, risk assessment for induction DDIs requires the use of whole cell systems with intact transcriptional and translational machinery as opposed to inhibition DDI studies that can be readily performed in human liver microsomes. The major molecular mechanisms of induction DDI involve binding to and activation of receptors that are involved in the regulation of transcription of genes encoding drug-metabolizing enzymes and/or transporters. Although many such receptors and transcriptional mechanisms have been identified as regulators of gene expression, the three receptors that mediate gene transcription that is induced in the majority of clinically relevant induction DDIs include (i) the aromatic hydrocarbon (Ah) receptor, (ii) the constitutive androstane receptor (CAR), and (iii) the pregnane X receptor (PXR). For a detailed overview of the molecular mechanisms of enzyme induction, the reader is referred to recent review articles [85–87].

The *in vitro* system that is currently considered as reliable for evaluating the potential for an NME to produce induction of drug-metabolizing enzymes is cultured human hepatocytes, either as primary cultures of fresh human hepatocytes or as attachable cryopreserved hepatocytes, as reflected in the recently published perspective of the PhRMA [88]. It is recommended for *in vitro* induction studies in human hepatocytes that the potential for an NME to produce induction of CYPs 1A2, 2B6, and 3A4 be evaluated, as the genes encoding these enzymes are considered to be representative sensitive targets that respond to induction via the AhR, CAR, and PXR, respectively. Significant overlap and cross talk between the CAR and PXR systems is well established, with coinduction of CYPs 2B6 and 3A4 by prototypic inducers such as rifampin. Accordingly, it was originally considered to be sufficient to test NMEs for potential for induction of CYPs 1A2 and 3A4, to enable risk assessment for induction DDIs that may result from increased expression of AhR and CAR/PXR target genes, respectively, as reflected in the recommendations in the 2006 FDA Draft Guidance [39]. However, more recent studies have indicated that although human PXR regulates both CYP3A4 and CYP2B6 with less selectivity, human CAR exhibits marked selectivity for CYP2B6 over CYP3A4 such that selective CAR activators can induce CYP2B6 substantially without appreciable levels of CYP3A4 induction [89]. Additionally, some inducers of CYP2B6 and CYP3A4 (e.g., carbamazepine, nevirapine, efavirenz) produce their effects primarily via CAR rather than PXR activation [90]. On the basis of these advances in our understanding of the molecular mechanisms of induction, it is now generally accepted that a comprehensive and definitive *in vitro* evaluation of risk for an NME to produce DDIs via CYP/transporter induction should include analysis of the potential for induction of CYPs 1A2, 2B6, and 3A4 in human hepatocytes [88], or in an appropriately qualified cell line that maintains inducible regulation via the AhR, CAR, and PXR mechanisms as also noted in the 2010 EMA Draft DDI guideline [31].

Although recognized as the gold standard *in vitro* system for induction DDI risk assessment, limitations do exist in the availability of high quality human hepatocytes as reproducibly performing biological reagents for *in vitro* induction assays. While interindividual variability in responsiveness still requires consideration, the challenges related to supply limitations and the intermittent availability of fresh human hepatocytes have been substantially offset by the availability of cryopreserved human hepatocytes

and establishment of experimental approaches that enable their reliable use as models for induction studies [91]. In an effort to qualify biological reagents for *in vitro* induction studies with reproducible performance characteristics that model the performance of high quality human hepatocytes, hepatocyte-derived cell lines have received considerable attention as surrogate models of human hepatocytes for *in vitro* induction studies.

Successful use of the immortalized hepatocyte cell line Fa2N-4 has been described in the *in vitro* assessment of enzyme induction for PXR target genes (e.g., CYP3A4, MDR1, CYP2C9) and AhR target genes (e.g., CYP1A2) [92], with promising *in vitro*–*in vivo* correlations to enable induction DDI predictions [93]. However, since this immortalized hepatocyte cell line does not express CAR, induction of CYP2B6 is not observed in response to CAR-selective inducers, and induction of CYP3A4 in Fa2N-4 cells following treatment with CAR-selective inducers is either blunted or absent when compared to cryopreserved human hepatocytes [94,95]. Additionally, the level of expression of several hepatic transporters in Fa2N-4 cells is substantially lower than in human hepatocytes. Specifically, expression of the uptake transporters OATP1B1 and OATP1B3 is substantially reduced, as a result of which the apparent potency for rifampin induction of CYP3A4 in Fa2N-4 cells is 10-fold lesser than that observed in cryopreserved human hepatocytes [94], consistent with rifampin being a substrate for OATP-mediated hepatic uptake, which regulates its intracellular concentrations and apparent induction potency [96]. Therefore, Fa2N-4 cells may represent a good surrogate for primary human hepatocytes for evaluating the potential for an NME to produce AhR- or PXR-mediated induction, but not CAR-mediated induction, limiting their utility as a definitive *in vitro* model for CYP induction studies in a drug development setting [88].

The differentiated hepatoma cell line HepaRG appears to be a promising surrogate for human hepatocytes, based on recent studies that have demonstrated expression, activity, and inducibility of CYPs 1A2, 2B6, and 3A4 [97,98], consistent with expression of AhR, CAR, and PXR under optimally cultured conditions [99]. Unlike Fa2N-4 cells, where CYP2B6 induction is not observed following treatment with CAR-selective inducers such as phenytoin or phenobarbital due to lack of CAR expression [94], induction of CYP2B6 by these inducers has been observed in HepaRG cells [98]. Additionally, an excellent correlation between parameters characterizing the maximum magnitude, potency, and efficiency of inducers ($E_{\max}$, EC_{50} , and $E_{\max}:EC_{50}$ ratio, respectively) in primary human hepatocytes versus HepaRG cells has also been described [100]. The experience gained from the above discussed examples of studies on the Fa2N-4 and HepaRG cell lines suggest that a comprehensive qualification of induction of CYPs 1A2, 2B6, and 3A4 using appropriate positive controls that measure regulation of all three pathways (AhR-, CAR-, and PXR-mediated induction) is critical to the use of any such cell line as a surrogate in place of primary human hepatocytes for *in vitro* induction studies.

Assays that measure binding to nuclear receptors and those that measure transactivation of reporter gene expression can be useful in the drug discovery setting due to their relatively higher throughput compared to definitive hepatocyte-based induction assays. Additionally, nuclear receptor transactivation assays can be useful in elucidating the molecular mechanism of the observed induction in hepatocytes (e.g., does an NME produce induction primarily via PXR or CAR activation?). However, since the mechanisms of induction are complex and involve multiple nuclear receptors with cross talk between the mechanisms, these assays alone are not considered sufficient in

excluding the potential for enzyme induction by an NME in drug development settings to support clinical DDI risk assessment [88].

3.6.2 Endpoints in *In vitro* Induction Studies

The general approach to *in vitro* induction studies in human hepatocytes (or adequately qualified cell lines with appropriate scientific justification of suitability, as discussed earlier) involves treatment with the NME for two to three days, with daily replacement of the culture medium containing the NME. Usually, a range of NME concentrations including the therapeutic systemic concentrations and including up to an order of magnitude higher concentration are evaluated to assess concentration response and the studies are conducted in hepatocytes from at least three different donor livers. At the end of the incubation period, the endpoints typically measured include (i) activity of CYPs 1A2, 2B6, and 3A4 *in situ* or in microsomes prepared from the hepatocytes using isoform-selective index reactions; and/or (ii) mRNA expression of CYPs 1A2, 2B6, and 3A4 using techniques such as reverse transcription-polymerase chain reaction [88]. Many CYP3A4 inducers are additionally time-dependent inhibitors of the enzyme's activity, making it important to include mRNA measurements in addition to enzyme activity assessments to aid appropriate mechanistic interpretation of the results, translation of relevance to the clinical setting, and appropriate clinical DDI study design, as reflected in the PhRMA perspective [88]. In fact, the EMA draft guideline mandates the inclusion of mRNA measurement in *in vitro* induction studies for the interpretation of study results if inhibition of the studied enzyme may not be excluded at the concentrations used or if a downregulation is suspected based on activity measurements [31]. A classical example of a drug producing complex simultaneous inhibition/induction effects is the HIV protease inhibitor ritonavir, with *in vitro* induction studies showing increases in mRNA expression of CYP3A4 due to PXR-mediated induction and decreased CYP3A4 activity due to time-dependent inactivation of the induced enzyme [101]. The clinical pharmacologic picture is consequently characterized by complex dose- and time-dependent interactions that are additionally dependent on the PK properties of the substrate drug. For example, in the case of the CYP3A substrate alprazolam, the net effect was a clinically significant level of inhibition of oral clearance (~2.5-fold increase in AUC) following short-term low dose treatment with four doses of 200 mg ritonavir administered BID, considered to be representative of a dosage schedule that may be used to initiate treatment with ritonavir [102]. In contrast, mild and clinically insignificant level of induction of alprazolam oral clearance (12% decrease in AUC) was observed as the net effect following a 10-day treatment with usual therapeutic dose of 500-mg BID of ritonavir as reflected in the ritonavir USPI [103]. Depending on the substrate drug's PK properties, the outcome of multiple-dose treatment with therapeutic doses of ritonavir can be variable, with substantial impairment of oral clearance (i.e., net inhibition rather than induction) observed even in the setting of a week-long treatment with high dose (500-mg BID) ritonavir for substrates such as sildenafil [104]. These consequences are obviously not straightforward to predict from the *in vitro* results alone, making it important to measure both mRNA and activity-based endpoints in the *in vitro* induction studies especially when there is a potential for concurrent inhibition. It is important to recognize that the use of CYP3A4 activity and/or mRNA measurement as an endpoint in *in vitro* induction studies is to serve as a sensitive marker of PXR-mediated induction and its associated pleiotropic

phenotype. For instance, if CYP3A4 induction is not observed in an *in vitro* induction study in human hepatocytes following treatment with an NME at concentrations up to 10 times the mean systemic $C_{\max}$ at clinically relevant doses, one can not only conclude that the risk for the NME to produce DDIs via CYP3A induction is low but also that the risk for it to produce DDIs via induction of other coinduced PXR targets such as CYPs 2C8, 2C9, 2C19, and MDR1 P-gp is also low as per the 2006 FDA Draft guidance [39]. With an NME that has properties such as ritonavir (i.e., PXR-mediated inducer and mechanism-based inactivator of CYP3A), if activity data alone were measured and used in risk assessment, it could result in a false negative risk assessment for induction DDIs. The conclusion that the risk for induction DDI is low may still be generally valid for potential interactions with CYP3A substrates since the net effect of inhibition may likely predominate and the time-dependent inhibition studies would lead to a clinical DDI evaluation of the effect of the NME on the PK of a sensitive CYP3A substrate to assess clinical relevance. However, a bigger impact is on risk assessment for induction of non-CYP3A targets of PXR, where a low risk for induction DDI with substrates of such enzymes or transporters (e.g., oral contraceptives, digoxin, warfarin) may be erroneously concluded in the absence of mRNA measurements that would be required for observing induction of gene expression, which would not be reflected by CYP3A4 activity measurements alone. Therefore, it is critical that the conclusion of lack of CYP induction be unbiased by factors such as concurrent inhibition or inactivation that could jeopardize the ability to pick up induction potential of an NME.

A recent analysis of CYP3A4 inducers evaluated the performance characteristics of mRNA versus enzyme activity as endpoints in cryopreserved human hepatocyte induction studies with respect to their sensitivity and specificity in the identification of the risk for induction DDIs and inferred that measurement of CYP3A4 mRNA levels represents the most sensitive endpoint for detecting induction in human hepatocytes [105]. Across inducers, the maximum fold increase in CYP3A4 mRNA expression observed in cryopreserved human hepatocytes was generally greater than the corresponding maximum observed fold increase in CYP3A4 catalytic activity [105], consistent with similar findings in a previous study using fresh human hepatocytes [100]. This is explained, at least in part, by concurrent inhibition of CYP3A4 by the inducer. Interestingly, when using mRNA expression of CYP3A4 as the endpoint, even with CAR-selective inducers such as phenytoin and phenobarbital, the fold increase in mRNA of CYP3A4 was consistently higher than the fold increase in mRNA of the other PXR/CAR-regulated drug-metabolizing enzymes examined (CYPs 2B6, 2C9, 2C19, 3A5), leading to the conclusion that CYP3A4 mRNA measurement may suffice as a single endpoint for evaluating risk for induction via the PXR and/or CAR pathways [105].

3.6.3 DDI Risk Assessment from *In vitro* CYP Induction Data

The translation of the results of *in vitro* induction studies performed in human hepatocytes (or adequately qualified cell lines that are responsive to PXR-, CAR-, and AhR-mediated induction, as discussed earlier) to clinical PK DDI risk assessment is an emerging area of science. Empirical cut-offs for fold increase in mRNA or activity over vehicle control and for the percentage of the observed induction by a strong inducer positive control (e.g., rifampin for CYP3A) tested alongside in the same experimental system have been used for classifying *in vitro* positives versus negatives for induction DDI risk assessment. For instance, observation of <40% of the positive

control's effect with use of a strong prototypic inducer as the positive control (e.g., rifampin for CYP3A) has been suggested as sufficient for classifying an NME as an *in vitro* negative for induction, eliminating the need for further clinical evaluation of DDI risk [14]. These approaches unfortunately lack a mechanistic basis and in the absence of a formal statistical optimization of the cut-off values for the specific experimental system, they should be used with caution. A recent study evaluated the performance characteristics of various preselected cut-offs for mRNA and activity endpoints in the categorization of risk for clinically relevant CYP3A induction DDIs using *in vitro* CYP3A4 induction data on 20 clinically significant CYP3A inducers and 15 noninducers in cryopreserved human hepatocytes [105]. This retrospective analysis concluded that a cut-off of fourfold increase in mRNA expression provided 98% sensitivity while maintaining a specificity of $\sim 70\%$ and importantly also demonstrated that the previously suggested cut-off of “40% of the positive control's effect” was associated with an unacceptably low sensitivity (i.e., high false negative rate) [105]. A similar observation questioning the conservativeness of the “40% of positive control” cut-off has been made in a previous study in primary human hepatocytes [106]. Opportunities exist for statistical refinement/optimization of empirical cut-offs using approaches such as receiver operator characteristics analyses that have been used with success in optimizing cut-offs for I:IC₅₀ ratios for assessment of risk for digoxin DDIs via P-gp inhibition [107].

3.6.4 Quantitative Predictions of Induction DDI Magnitude

For a detailed overview of approaches to quantitative IVIVE of induction DDIs, the reader is referred to a recent review article [108]. The first step in this process is to characterize the concentration–effect relationship for the induction observed *in vitro* (either for the mRNA increase and/or increase in enzyme activity), which is typically accomplished using a typical $E_{\max}$ model. IVIVE is then performed assuming that the fold increase in enzyme expression or activity estimated from the *in vitro* concentration–effect relationship at the *in vivo*–relevant concentration of the inducer directly translates to fold increase in intrinsic clearance of metabolism via the induced enzyme *in vivo* [109]. For an orally administered object drug without appreciable intestinal extraction (or under the assumption of lack of meaningful effect of the inducer on its intestinal extraction ratio), the following equation mechanistically allows the translation of the estimated *in vitro* concentration–effect relationship to a predicted interaction magnitude and is essentially similar in form to Equation 3.4 that was presented previously for inhibition DDI:

$$\frac{AUC_{\text{induced}}}{AUC_{\text{control}}} = \frac{1}{(1 - f_{\text{m(CYPi)}}) + \left(f_{\text{m(CYPi)}} \cdot \left(1 + \frac{E_{\max}[\text{Ind}]}{EC_{50} + [\text{Ind}]} \right) \right)} \quad (3.11)$$

With enzyme activity as the endpoint in the *in vitro* induction assay in fresh human hepatocytes, use of unbound systemic steady-state maximum concentration of the inducer to estimate [Ind] and use of unbound EC₅₀ of the inducer *in vitro* (calculated from the *in vitro* induction EC₅₀ and the measured unbound fraction of the inducer in hepatocytes), Equation 3.11 has been successfully used to predict the magnitude of CYP3A induction DDIs [106]. Interestingly, when mRNA expression rather than enzyme activity was used as the *in vitro* endpoint, the performance of

IVIVE was poorer, with a trend for overprediction of the magnitude of clinical DDIs, explained by a higher $E_{\max}$ for mRNA expression compared to enzyme activity as the *in vitro* endpoint. This is not surprising considering that the fold increase in mRNA (a measure of the extent of induction) may not necessarily quantitatively equal the fold increase in enzyme content (which is governed by the efficiency of mRNA translation to protein), which ultimately determines enzyme activity. Nevertheless, this does not necessarily mean that enzyme activity rather than mRNA is a better endpoint for concentration–effect analysis of *in vitro* induction data to enable IVIVE. As discussed earlier, since certain CYP3A inducers also produce some level of inhibition of the enzyme’s activity either via reversible or time-dependent mechanisms, an advantage of the mRNA endpoint is that it is a “pure” reflection of the induction effect unbiased by effects of the inducer on enzyme activity, the IVIVE of which should ideally be performed using approaches previously discussed for inhibition DDIs. If, however, mRNA is used as the endpoint, since a one-to-one correspondence between fold increase in mRNA and fold increase in enzyme content/activity cannot be assumed, there is a need for introducing an empirical scalar (multiplicative adjustment factor on $E_{\max}$ in Equation 3.11) that can be derived using a calibration approach using positive controls within the same experimental system, as has been described by Fahmi and colleagues [83]. In their model, Fahmi and colleagues additionally consider induction of intestinal metabolism, as well as concurrent reversible inhibition and time-dependent inhibition, taken together in the extrapolation of net *in vivo* DDI magnitude using a more general form of Equation 3.10 where the composite multiplicative effect of the inhibition, inactivation, and induction of intrinsic clearance of the affected enzyme is considered [83].

In addition to the above discussed mechanistic/semimechanistic IVIVE approaches to the prediction of induction DDIs, empirical *in vitro*–*in vivo* correlation approaches have also been described. These approaches involve establishment of a descriptive correlation relating the *in vitro* induction data and clinical exposures of the inducer to the observed clinical DDI magnitude for a database of prototypic inducers using a fit-for-purpose empirical mathematical model. Such a model is developed from a database of *in vitro* induction parameters, human exposure information, and clinical DDI outcomes. It is intended to provide a quantitative knowledge management framework that can aid forecasting of the clinical DDI magnitude associated with an NME from *in vitro* induction results and human exposure of the NME at clinically relevant doses (or predicted human exposures, if applied before entry into humans). With the immortalized cell line Fa2N-4 as the *in vitro* system, Ripp and colleagues described application of a relative induction score (RIS) approach for predicting the magnitude of clinical DDIs of inducers with midazolam (sensitive CYP3A substrate) and ethinyl estradiol (substrate for CYP3A as well as other PXR-inducible enzymes) [93]. The parameters $E_{\max}$ and EC_{50} describing the concentration–effect relationship for the fold increase in CYP3A4 mRNA *in vitro* were estimated for each inducer. The RIS for each inducer in the database was then calculated by substituting the unbound clinical $C_{\max}$ of the inducer for the concentration term into the estimated *in vitro* concentration–effect relationship for CYP3A4 induction. The RIS therefore is simply a calculated fold increase in CYP3A4 mRNA at the unbound $C_{\max}$ of the inducer based on the concentration–effect relationship characterized for the inducer *in vitro*. The relationships between the RIS and percent decrease in object drug (midazolam or ethinyl estradiol) AUC were fitted to empirical sigmoid $E_{\max}$ models. These models provide quantitative frameworks to guide prediction of clinical DDI magnitude with

midazolam and ethinyl estradiol from *in vitro* induction parameters (EC_{50} and E_{max}) and the NME's clinical PK data [93]. Although first described using Fa2N-4 cells as the *in vitro* model, the RIS approach has been subsequently qualified as applicable using cryopreserved human hepatocytes as well [110]. Using HepaRG cells as the *in vitro* model, Kanebratt and Andersson described an *in vitro*–*in vivo* correlation relating the ratio of total systemic exposure (AUC) of the inducer to the concentration of the inducer that produced a twofold increase in mRNA expression of CYP3A4 *in vitro* (F_2) as the predictor variable and the clinical DDI magnitude expressed as percent decrease in AUC of a selective and sensitive CYP3A substrate as the dependent variable. Similar to the RIS-based approach, the relationship between the AUC/F_2 ratio and percent decrease in object drug AUC was fitted to a hyperbolic E_{max} model to provide a quantitative framework to guide prediction of clinical DDI magnitude from *in vitro* induction data (F_2) and clinical exposures (AUC) of an NME [98].

3.7 NME AS PRECIPITANT: CLINICAL PHARMACOLOGIC EVALUATION

The key goal of the *in vitro* DDI risk assessment program evaluating the effects of an NME on the activity and expression of CYP enzymes is to guide development of a scientifically appropriate clinical DDI evaluation strategy. Importantly, the *in vitro* data are utilized to eliminate the need for unnecessary DDI studies in cases where it can be concluded that there is a remote possibility of a DDI via CYP inhibition or induction based on the CYP-inhibitory potency or concentration response for CYP induction viewed in the context of clinical exposures of the NME. For instance, there are many recent examples of approved drugs across therapeutic areas where an $I:K_i$ ratio of <0.1 (Fig. 3.2) has been used to conclude that clinical DDIs via inhibition of the particular CYP isoform are unlikely without the need for specific clinical DDI studies. When the *in vitro* data cannot be used to exclude the risk for a potential DDI, prioritization of clinical DDI studies is necessary such that the conduct of clinical DDI studies that are more likely to result in clinically meaningful interactions is planned ahead of the conduct of less critical DDI studies that may result in smaller magnitude interactions.

For CYP-inhibitory DDIs, developing the strategy for clinical pharmacologic evaluation of DDIs is performed using the rank-order approach [22,23], a central assumption of which is that the rank order of potencies of inhibition of multiple CYP isoforms by an NME will be preserved *in vivo* such that the rank order of clinical DDI magnitude with isoform-selective probe substrates would be similar to the rank order of *in vitro* potencies versus each of those enzymes. The use of this approach in guiding clinical DDI strategy is illustrated schematically in Fig. 3.6. Consider, for example, a situation where an NME produces concentration-dependent *in vitro* inhibition of multiple CYP isoforms (*A* through *E*), with *A* being the most potently inhibited enzyme (lowest IC_{50}) followed by *B*, *C*, *D*, and *E* in that order. In such a situation, since *A* is the most potently inhibited enzyme, the clinical pharmacology plan should typically consider a DDI study with a probe substrate for enzyme *A* as the first clinical DDI study. If the results of this DDI study indicate the absence of an interaction, it would not be necessary to conduct DDI studies with probe substrates for enzymes *B*–*E* since they are less-potently inhibited *in vitro* and the resulting clinical DDI magnitude would

Figure 3.6 Rank-order approach for developing clinical DDI evaluation strategy based on *in vitro* CYP inhibition potency data.

therefore be expected to be lesser than that observed on inhibition of enzyme A. If, however, the clinical DDI study evaluating the effect of the NME on a selective probe substrate for enzyme A reveals a clinically meaningful interaction, the next DDI study to be considered is with a probe substrate for enzyme B (the enzyme with the second lowest IC_{50}), with the need for a DDI study with a probe substrate of enzyme C evaluated based on the results of the DDI study with the substrate of enzyme B. This iterative process is repeated until the lack of a clinical DDI is demonstrated, at which point it can be concluded that no additional DDI studies are necessary. This is analogous to a bridging approach where the first DDI study demonstrating the lack of an interaction serves as the link between the *in vitro* and clinical settings, enabling extrapolation of the *in vitro* data for less-potently inhibited enzymes to the conclusion that clinical DDIs via inhibition of these enzymes is unlikely. The fidelity of the rank-order approach has been retrospectively examined by Obach and colleagues [22,23] from a primary *in vitro* database of CYP isoform-specific inhibitory potency data for 21 drugs for which the results of clinical DDI studies with selective substrates of at least 3 CYP isoforms were available in the published literature. A twofold clinical DDI magnitude (i.e., ratio of exposure of the probe substrate in the presence of the CYP inhibitor in reference to that observed in the absence of the CYP inhibitor) was used to categorize an interaction as positive for purposes of this exercise. This analysis indicated that in 18 out of the 21 cases examined, retrospective application of the above described iterative rank-order approach would have been successful, supporting the performance of this strategy to define the clinical DDI strategy in a drug development setting.

There is precedence for the use of the rank-order approach to inform regulatory decision making. For example, *in vitro* CYP inhibition studies indicated that temsirolimus is an inhibitor of both CYP2D6 ($I:K_i$ ratio of 0.38) and CYP3A4 ($I:K_i$ ratio

of 0.19) [111]. A clinical DDI study was performed to evaluate the effect of temsirolimus at the clinically recommended dose of 25 mg on the PK of the CYP2D6 substrate desipramine. This study concluded the lack of an effect of temsirolimus at the recommended clinical dose on CYP2D6 activity in humans based on 90% confidence intervals for the ratio of geometric least square means of desipramine AUC and $C_{\max}$ (when administered with temsirolimus in reference to when administered alone) being contained within the 80–125% range [112]. The Clinical Pharmacology Review of the temsirolimus NDA concluded that based on the $I:K_i$ ratios from *in vitro* studies, if temsirolimus did not produce clinically meaningful inhibition of CYP2D6, it can be extrapolated that temsirolimus would not inhibit CYP3A *in vivo* [111]. Accordingly, the USPI for temsirolimus indicates that no clinically significant effect is anticipated when temsirolimus is coadministered with agents that are metabolized by CYP2D6 or CYP3A4 [113]. Another example illustrating the application of the rank-order approach is for the Bcr-Abl kinase inhibitor nilotinib. Nilotinib was an *in vitro* inhibitor of multiple human liver microsomal CYP isoforms including CYPs 2C9, 2C8, 3A, 2D6, and 2C19 in decreasing order of potency, with corresponding $I:K_i$ ratios of 32.6, 18.2, 9.6, 2.9, and 1.1, respectively, calculated using the mean steady-state $C_{\max}$ of nilotinib at the recommended dose of 400 mg BID as the measure of $[I]$ [114]. As the clinical DDI implications of these *in vitro* observations were not fully elucidated at the time of approval of this anticancer agent, follow-up clinical DDI evaluation was required as a phase 4 postapproval commitment. On the basis of the observed rank order of CYP-inhibitory potency indicating inhibition of CYP2C9 with the highest potency, it was recommended in the Clinical Pharmacology Review of the nilotinib NDA that the sponsor conduct a DDI study evaluating the effect of multiple-dose administration of nilotinib on the PK of a sensitive CYP2C9 substrate (e.g., *S*-warfarin). Further, it was indicated that if a significant interaction was demonstrated, additional DDI studies evaluating the effects of multiple-dose administration of nilotinib on the PK of a sensitive CYP2C8 substrate and/or a sensitive CYP3A substrate may be needed [114], suggesting application of the rank-order approach in defining the appropriate clinical DDI evaluation strategy based on the results of *in vitro* CYP inhibition studies.

It is important to note that the rank-order approach is not without assumptions: one, is that the factors that determine quantitative translation of the *in vitro* K_i to the magnitude of the clinical DDI are similar across all CYP isoforms. However, this may not be the case when comparing across enzymes that may be expressed in the small intestine and liver (e.g., CYP3A) and those that are mainly expressed in the liver (e.g., other CYP isoforms). This is because inhibition of intestinal presystemic extraction of the probe drug can contribute to the overall magnitude of the observed interaction via CYP3A inhibition in addition to the impact of inhibition of hepatic metabolism, depending on the baseline F_G of the probe (Eq. 3.5). Consider, for example, an NME that inhibits CYP1A2 and CYP3A4, with a marginally greater potency of inhibition of CYP1A2 versus CYP3A4. If a DDI study with a sensitive CYP1A2 substrate (e.g., caffeine) demonstrates lack of an interaction, the possibility of *in vivo* inhibition of CYP3A may still be difficult to completely exclude for orally administered CYP3A substrates subject to substantial intestinal extraction (e.g., midazolam, simvastatin, buspirone). This is because the rank order of $I:K_i$ ratio using systemic $C_{\max}$ of the NME as the estimate of $[I]$ may not directly translate to the rank order of *in vivo* DDI magnitude due to the impact of higher intestinal concentrations of the inhibitor that may contribute to a greater effect on the PK of an orally administered CYP3A substrate

than would be expected based on considerations of systemic exposure alone. It is of interest that the 2010 EMA DDI Draft Guideline specifically addresses this caveat of the rank-order approach and does not permit extrapolation of the lack of inhibition *in vivo* for orally administered CYP3A substrates based on a lower potency of CYP3A inhibition and lack of an *in vivo* interaction with a probe substrate of a more potently inhibited enzyme [31]. Despite this caveat and the recommendation to avoid extrapolation to CYP3A for orally administered substrates, the rank-order approach, nevertheless, provides a useful framework to streamline clinical development planning by guiding clinical DDI strategy, prioritizing the conduct of clinical DDI studies and eliminating the need for unnecessary studies.

3.7.1 Probe Substrate Drug Selection in Clinical DDI Studies

A critical decision in clinical DDI study design for the evaluation of the CYP-inhibitory or inducing effect of an NME is selection of the probe substrate of the affected enzyme. Ideally, the probe drug should be a sensitive and selective substrate of the enzyme whose inhibition or induction by the NME is being investigated *in vivo*. A probe drug can be considered a sensitive substrate of a CYP enzyme if its exposure has been shown to increase greater than or equal to fivefold by a known inhibitor of that enzyme [39]. The reason it is important to select a sensitive probe substrate is because if lack of interaction is demonstrated with a sensitive substrate, it can be presumed that less sensitive substrates will also be unaffected, eliminating the need for conducting additional DDI studies to evaluate the potential clinical relevance of DDIs with less sensitive (but perhaps more clinically relevant) coadministered agents that are metabolized by the same enzyme as the probe drug. Consider, for instance, the drugs theophylline and caffeine. Both methylxanthine derivatives are substrates of CYP1A2, with a major portion of their clearance mediated via oxidative metabolism by this enzyme. It is estimated that ~95% of *in vivo* clearance of caffeine is via CYP1A2-mediated metabolism, whereas the relative contribution of CYP1A2 to theophylline clearance is lower, with an estimated contribution of ~80% as inferred from the results of human radiolabeled mass balance/metabolism and *in vitro* reaction phenotyping studies [49]. As indicated by Equation 3.4, the maximum possible magnitude of a DDI resulting from inhibition of CYP1A2 with caffeine as the substrate ($f_{m(CYP1A2)}$ of ~0.95) would be ~20-fold, whereas this ceiling for maximum possible magnitude of a CYP1A2-inhibitory DDI with theophylline ($f_{m(CYP1A2)}$ of ~0.8) would be calculated to be ~5-fold. Accordingly, DDI studies with the strong CYP1A2 inhibitor fluvoxamine have revealed a 5- to 12-fold decrease in caffeine oral clearance on coadministration with fluvoxamine [115,116], while the effects of fluvoxamine on theophylline AUC are more modest, characterized by an ~3-fold increase in AUC [117,118]. Although theophylline has a narrow therapeutic range and the consequences of inhibition of its clearance by an NME would be greater from a medical standpoint compared to the implications of impairment of caffeine clearance, the above discussed scientific considerations justify the use of caffeine rather than theophylline as a sensitive CYP1A2 probe substrate in the design of clinical DDI studies aimed at evaluating an NME as a potential inhibitor of this enzyme. If a caffeine DDI study establishes the lack of an interaction, it can be presumed that the exposure of theophylline will not be affected by the NME due to the greater sensitivity of caffeine compared to theophylline as a CYP1A2 substrate *in vivo* and conduct of a

theophylline DDI study would be unnecessary. In contrast, if the exposure of caffeine is increased meaningfully (e.g., greater than or equal to twofold), it cannot be presumed that the PK of theophylline will be unaffected. If the NME is being developed in a therapeutic area or patient population where coadministration with theophylline is likely, it may be necessary from a medical standpoint to conduct a DDI study with theophylline to quantify the magnitude of the specific interaction and provide prescribing guidance.

When dealing with CYP3A, due to the expression of the enzyme both in the liver and in the small intestine, the sensitivity of a probe substrate of this enzyme depends not only on the contribution of CYP3A to the overall hepatic metabolism of the probe but also on the extent of contribution of intestinal CYP3A to its presystemic extraction following oral administration (Eq. 3.5). Therefore, two critical parameters: $f_{m(\text{CYP3A})}$ and F_G determine the sensitivity of substrates of CYP3A. Consider, for example, three substrates of CYP3A: midazolam, alprazolam, and buspirone. The rank order of sensitivity of these three drugs to CYP3A-inhibitory DDIs is as follows: buspirone > midazolam > alprazolam. This is readily apparent on examination of Fig. 3.7, where the effects of various CYP3A inhibitors (ketoconazole, itraconazole, grapefruit juice, nefazodone, erythromycin, diltiazem, verapamil, and ritonavir) on midazolam AUC on the X-axis is compared against their corresponding effects on buspirone (circle symbols) or alprazolam (square symbols) AUC on the Y-axis. This analysis indicates that alprazolam is generally less sensitive to CYP3A inhibition than midazolam (square symbols are below the line of identity) but that buspirone is generally more sensitive than midazolam (circle symbols are above the line of identity). These observations are explained by the PK properties of these object drugs, with differences in sensitivity of buspirone and midazolam being explained by buspirone having a smaller F_G than midazolam (0.21 versus 0.5) and differences in the sensitivity of alprazolam and midazolam being explained by differences in $f_{m(\text{CYP3A})}$ (alprazolam: 0.74, midazolam: 0.93) as well as F_G (alprazolam: 0.99, midazolam: 0.5). Clearly, CYP3A is a major contributor to alprazolam clearance *in vivo* such that coadministration with strong inhibitors such as ketoconazole can result in clinically significant increases in alprazolam exposure of approximately fourfold increase in AUC [119] with such coadministration not recommended in clinical practice [120]. However, alprazolam is not a sufficiently sensitive CYP3A substrate and is therefore not a suitable probe for evaluating the potential CYP3A inhibitory effect of an NME in a clinical DDI study. In contrast, both midazolam and buspirone represent sensitive probe substrates of CYP3A for use in clinical DDI studies as coadministration with CYP3A inhibitors (e.g., ketoconazole, ritonavir, itraconazole) has resulted in fivefold or greater magnitudes of DDI with these substrates (Fig. 3.7).

Examples of selective probe substrates for the major human drug-metabolizing CYP isoforms include caffeine and tizanidine for CYP1A2; omeprazole for CYP2C19; desipramine for CYP2D6; and midazolam, triazolam, buspirone, simvastatin, and felodipine for CYP3A [39]. For some CYP isoforms, established sensitive probe substrates are lacking and in these cases, representative reasonably selective substrates will need to be used. In some cases, although the clinically dosed substrate drug is a racemic mixture, the PK of specific enantiomers will need to be characterized using chiral bioanalytical methods due to stereoselective metabolism of individual enantiomers by specific enzymes. For example, although racemic warfarin is administered as the probe substrate for evaluation of CYP2C9 inhibitory effect of an NME, the PK of *S*-warfarin will need to be characterized as only this enantiomer is

Figure 3.7 Illustration of differential substrate sensitivity to metabolic inhibitory DDIs, based on examination of the effects of different CYP3A inhibitors on the AUCs of three representative CYP3A substrate object drugs midazolam, alprazolam, and buspirone. The squares indicate the relationship between the effects of these inhibitors on alprazolam AUC (Y-axis) and their corresponding effects on midazolam AUC (X-axis). The circles indicate the relationship between the effects of these inhibitors on buspirone AUC (Y-axis) and their corresponding effects on midazolam AUC (X-axis). The line represents the line of identity ($X = Y$). The CYP3A inhibitors included are diltiazem (DIL), erythromycin (ERY), single-strength grapefruit juice (GFJ), chronic double-strength grapefruit juice (GFJ, chronic DS), itraconazole (ITR), ketoconazole (KET), nefazodone (NEF), and ritonavir (RIT).

selectively metabolized by CYP2C9 [31]. Finally, in some cases, specific pathways of metabolism of the probe substrate (as opposed to total clearance) are known to be selectively catalyzed by the enzyme of interest because of the existence of additional metabolic pathways catalyzed by other enzymes. In these cases, a metabolite/parent exposure ratio rather than parent drug AUC is used as the endpoint for DDI studies. For example, hydroxylation of the antidepressant bupropion is a specific index of CYP2B6 activity, as supported by *in vitro* metabolism studies of this pathway in human liver microsomes and using recombinantly expressed human CYP isoforms [121]. Consistently, use of the hydroxybupropion/bupropion exposure ratio as an endpoint in clinical DDI studies is supported by its ability to identify the CYP2B6 inhibitory potential of the antiplatelet agents, ticlopidine and clopidogrel, that produced 90% and 70% decrease, respectively, in the hydroxybupropion/bupropion AUC ratio [122].

3.8 NME AS OBJECT OF DDI

The preceding sections of this chapter have provided an overview of the approaches used for assessment of the risk for DDIs produced by the NME as the precipitant drug and their clinical pharmacologic evaluation, either as a potential inhibitor or inducer of the mechanisms of disposition of coadministered agents. The scientific considerations

underlying risk assessment for DDIs resulting from modulation of disposition of the NME and strategies for their clinical pharmacologic evaluation in drug development will now be discussed using representative examples.

3.8.1 Determinants of DDI involving the NME as the Object Drug

The cornerstone for assessment of risk for PK DDIs for an NME as the object drug is a quantitative understanding of the relative contributions of each mechanism to total human clearance at the level of its specific molecular determinants, that is, specific enzyme or transporter isoforms, denoted variably by f_m , $f_{m(\text{CYP})}$, $f_{m(\text{CYPi})}$, or the CR in previous investigations of CYP-based DDIs [22,44–48,123,124], as is evident from the previously discussed Equations 3.4 and 3.11. Derivation of the $f_{m(\text{CYPi})}$ for an NME to define the contribution of a specific enzyme to its overall clearance is a two-step process. The first step involves an estimation of the *in vivo* contribution of specific biotransformation pathways to total drug clearance in humans, and the second step involves an estimation of the relative contribution of specific enzyme isoforms to each of these *in vivo* biotransformation pathways using *in vitro* reaction phenotyping approaches. The preferred approach for the first step of this two-step process is a radiolabeled mass balance study that includes identification and quantification of metabolites recovered in excreta (urine and feces) to enable construction of the overall human biotransformation scheme for the NME and estimate relative contributions of each primary biotransformation pathway to the overall clearance of the drug [125]. The second step involves an *in vitro* analysis of the principal biotransformation pathways identified in the first step, using an appropriate *in vitro* system that models human biotransformation of the NME, to define the relative contribution of each molecular determinant (e.g., CYP isoform) to the clearance of the NME via that biotransformation pathway. The results from these two distinct steps will need to be integrated to derive the $f_{m(\text{CYPi})}$ for each contributing enzyme isoform to enable DDI risk assessment for the NME as the object drug. For example, if two primary biotransformation pathways A and B are identified for an NME based on analysis of excretory metabolites in a radiolabeled mass balance study, with relative contributions of 30% and 60% to total clearance, and if reaction phenotyping studies on pathways A and B indicate 30% and 50% contributions of CYP3A, respectively, it can be inferred that ~40% of the total clearance of the NME is expected to occur via CYP3A-mediated metabolism (calculated as the sum of 30% of 30% for pathway A and of 50% of 60% for pathway B). Similarly, if the reaction phenotyping studies indicate that the contributions of CYP2D6 to pathways A and B are 50% and 10%, respectively, it can be inferred that ~20% of the total clearance of the NME is expected to occur via CYP2D6-mediated metabolism.

3.8.2 Strategy for Clinical DDI Evaluation

On the basis of current regulatory guidance [31,39], clinical DDI studies evaluating the effects of strong inhibitors/inducers of a participating enzyme are not necessary if the relative contribution of the enzyme to overall clearance is <25%. Accordingly, in the above discussed scenario, the clinical pharmacology plan for such an NME should typically include DDI studies with a strong CYP3A inhibitor (e.g., ketoconazole) and strong CYP3A inducer (e.g., rifampin), whereas studies evaluating the effect of a strong

CYP2D6 inhibitor (e.g., paroxetine) or of the impact of the CYP2D6 polymorphism (e.g., EM vs. PM study) would not be required, as a complete inhibition of CYP2D6 or lack of activity of this enzyme would not be expected to result in a clinically meaningful exposure alteration (contribution <25% would translate to a <1.33-fold increase in exposure on complete inhibition of the enzyme, based on Equation 3.4).

If more than one enzyme is predicted to contribute meaningfully (>25%) to the overall clearance of an NME, DDI studies with strong inhibitors and inducers of each of these pathways should be typically planned. However, a step-wise approach can be used starting with the DDI study evaluating the effect of a strong inhibitor of the highest contributor enzyme followed by conduct of DDI studies with strong inhibitors of the less important contributors (analogous to the rank-order approach described earlier for CYP inhibition studies for the NME as the inhibitor). For each of the contributing enzymes, if a strong inhibitor produces a large and clinically meaningful increase in NME exposure, the need for additional DDI studies with less potent (e.g., moderate) inhibitors of that enzyme will need to be considered to guide DDI risk management and inform prescribing guidance. An example that illustrates this is for the CYP3A substrate everolimus, where the results of DDI studies with strong and moderate CYP3A inhibitors have informed prescribing guidance [126]. The value of such characterization in informing prescribing guidance is discussed later. If a contributing enzyme is polymorphically expressed, with existence of PM genotypes that are deficient in enzyme activity, a PK study evaluating the effect of the polymorphism on the NME's PK (e.g., in EMs vs PMs) can serve the purpose of a DDI study with a strong inhibitor and an additional strong inhibitor DDI study would not be necessary. However, it is important to note that patients with PM genotypes for the major molecular determinant of clearance of the NME may still be at risk of DDIs resulting from inhibition of the alternative "minor" clearance mechanism(s). Although these alternative clearance pathways may be considered minor contributor(s) to total clearance in EMs, they will be important contributor(s) in PMs. For example, consider a drug that is cleared primarily via metabolism by the polymorphic enzyme CYP2D6 ($f_i(\%)$ 80%), with the remainder of its clearance occurring via metabolism by CYP1A2. Although CYP2D6 EMs will not be at risk of DDIs via inhibition of CYP1A2, it is important to note that clinically relevant increases in exposure to the NME can still be produced by CYP1A2 inhibitors (e.g., fluvoxamine) in the CYP2D6 PM subpopulation. As will be discussed later, population-based simulations integrating *in vitro* quantitative metabolism phenotyping data together with the available clinical PK characteristics of the NME in EM and PM subpopulations represent a powerful approach to DDI risk forecasting in such special populations and can additionally inform the need for and design of DDI studies in such special subpopulations.

3.8.3 Risk Assessment Strategies in Early Clinical Development

Although the above described two-step process that requires data from a human radiolabeled mass balance study is the gold standard approach for definitive DDI risk assessment and development of the clinical DDI strategy for the NME as the object drug, it is not always practically feasible in early clinical development planning to complete a radiolabeled mass balance study ahead of initiation of clinical development in patient populations (i.e., ahead of phase 2 proof-of-concept clinical studies). Nevertheless, early assessment of DDI risk is necessary to enable appropriate risk management

strategies in clinical studies in patient populations. Some key questions that will need to be answered include: (i) Are certain DDIs expected to be either large in magnitude or clinically meaningful (e.g., with strong inhibitors of an enzyme that is expected to be a major contributor to clearance of the NME), to require exclusion of specific categories of concomitant medications? (ii) Is the expected magnitude and clinical significance of certain DDIs small enough to permit inclusion of patients on certain concomitant medications (e.g., patients on weak or moderate inhibitors of a contributing enzyme) provided adequate safety monitoring is included? (iii) Is there advice that can be provided on alternate concomitant medications within a particular therapeutic category that may be best suited from the standpoint of DDI risk minimization (e.g., sertraline or citalopram in place of paroxetine or bupropion as a selective serotonin reuptake inhibitor antidepressant for an NME that is expected to be metabolized by CYP2D6; azithromycin or amoxicillin as potential antibiotics in place of clarithromycin for an NME that is expected to be metabolized by CYP3A). In oncology drug development, DDI risk assessment and the development of risk management strategies will need to begin sooner than in many other therapeutic areas considering that phase 1 first-in-human studies are commonly done in patients with advanced cancer that are often on multiple concomitant medications, especially when dealing with cytotoxic NMEs that cannot be studied in healthy volunteers [127]. Therefore, from a practical standpoint, alternate methods for an earlier provisional estimation of $f_{m(CYPi)}$ are often necessary before initiation of phase 2 clinical studies, and in some cases, possibly even ahead of first-in-human studies if drug development is to initiate in patient populations. *In vitro* metabolite profiling and identification studies using radiolabeled substrate and human biomaterials (e.g., human liver microsomes, hepatocytes, S9 fractions) are generally successful in identifying the primary biotransformation pathways of drugs in humans [128]. To enable identification of the primary biotransformation pathways in humans with reasonable confidence in the absence of data from a human mass balance study, a bridging approach may be used that leverages *in vitro* and *in vivo* metabolism data from preclinical species using radiolabeled NME together with *in vitro* metabolite profiling using human biomaterials. The observation of *in vitro* to *in vivo* correspondence in the biotransformation pathways of the NME in preclinical species (e.g., rat, dog) can increase confidence in use of *in vitro* metabolite profiling studies using human biomaterials (e.g., human liver microsomes, human hepatocytes) to estimate the contributions of individual metabolic pathways (e.g., oxidative vs conjugative) to overall human clearance and identify pathways of importance. These data can then be used to design *in vitro* quantitative reaction phenotyping studies of the principal biotransformation pathways to estimate the relative contributions of individual enzyme isoforms to the overall clearance of the NME.

3.8.4 Quantitative Reaction Phenotyping of NME Metabolism

Irrespective of the approach used to defining the contribution of specific biotransformation pathways to NME clearance (*in vivo* radiolabeled mass balance study in humans as the gold standard vs a provisional estimate using radiolabeled *in vitro* metabolite profiling studies with human biomaterials), the second step of the two-step process of estimating $f_{m(CYPi)}$ involves quantitative reaction phenotyping of the principal biotransformation pathways. *In vitro* drug metabolism studies have reached an impressive level of sophistication to permit derivation of a quantitative phenotype

(i.e., description of the percent contributions of each enzyme to total metabolism *in vitro*) of CYP-mediated biotransformation of drug candidates. This is possible using the complementary approaches of selective chemical and/or antibody-mediated inhibition, scaling from kinetic studies on recombinantly expressed individual CYP isoforms, and correlation analyses of metabolic rates of the NME against the content/activity of individual CYP isoforms in a panel of human liver microsomes. A detailed overview of reaction phenotyping strategies and experimental approaches is not within scope of this chapter, and the reader is referred to review articles on the subject [14,129–134].

Although the *in vitro* prediction of *in vivo* glucuronidation-mediated clearance and reaction phenotyping of conjugative metabolism is an emerging area of science, significant progress has been made in recent years with availability of recombinantly expressed uridine diphosphate glucuronosyltransferase (UGT) isoforms, characterization of isoform-selective substrates/index reactions, and limited examples of isoform-selective inhibitors [135]. For example, optimization of experimental conditions for successful quantitative phenotyping of the relative contributions of parallel pathways of direct glucuronidation versus oxidative CYP-mediated metabolism to the overall metabolism of drugs has been recently described [136]. Once the relative contribution of glucuronidation to total hepatic metabolism is defined using such an approach, the relative contribution of specific molecular determinants can be further assessed with the use of recombinantly expressed UGT isoforms, with the use of selective UGT inhibitors where available, and with studies using genotyped liver microsomal samples for UGTs displaying polymorphic expression. A recent example of such an application is the use of kinetic studies on human liver microsomes with functional UGT2B17 (*1/*1 genotype) versus UGT2B17-deficient liver microsomes (*2/*2 genotype) coupled with kinetic studies of recombinantly expressed UGT isoforms to reveal an important contribution of UGT2B17 to the metabolism of the histone deacetylase inhibitor anticancer drug vorinostat [137]. Application of a two-stage approach involving (i) estimation of the relative contribution of glucuronidation versus CYP-mediated metabolism to total metabolic clearance and (ii) reaction phenotyping of the glucuronidation and oxidation components, should therefore permit derivation of initial estimates of the contribution of each molecular determinant (i.e., individual UGT and CYP isoforms) to the overall hepatic clearance of an NME.

3.8.5 Considerations of Pharmacokinetic Properties of the NME in Risk Assessment

Factors that need to be considered in translational assessment of the level of DDI risk include the route of administration and the expected hepatic extraction ratio. For intravenously administered high clearance drugs, clearance is largely dependent on hepatic blood flow, and the PK of such drugs will therefore be relatively less sensitive to alterations in hepatic metabolic intrinsic clearance by coadministered inhibitors or inducers of metabolic enzymes. In contrast, intravenously administered low clearance drugs whose clearance is largely dependent on hepatic intrinsic clearance are relatively less sensitive to changes in hepatic blood flow and will be more sensitive to DDIs via inhibition of hepatic metabolism [138]. Unlike intravenously administered drugs, the systemic exposures of orally administered drugs that are primarily cleared via the hepatic route will be equally sensitive to DDI via inhibition of hepatic metabolism irrespective of their baseline extraction ratio. However, the specific

nature of the PK interaction (i.e., change in shape of the oral dose PK profile due to a DDI) will be different, with the half-life being altered (reflecting alteration of systemic clearance) without an appreciable change in peak plasma concentrations for low clearance drugs and the peak concentrations being principally affected (reflecting an alteration of bioavailability) without an appreciable alteration of half-life for high clearance drugs. Additionally, when CYP3A is identified as a contributor to the human liver microsomal metabolism of an NME, intestinal first-pass extraction of the NME can occur following oral administration, inhibition of which can increase DDI magnitude beyond what would be predicted solely from the *in vitro* liver microsomal metabolic phenotype. Considering the above discussed multiple factors (route of administration, extraction ratio, intestinal extraction, etc.) that influence translation of $f_{m(CYPi)}$ to the projected maximum DDI magnitude, physiologically based IVIVE permits integration of all available data on the NME and inhibitor of interest, to predict clinical DDI magnitude [124,139], as will be discussed later.

3.8.6 Considerations of Transporter Contribution to NME Disposition

Uncertainty in the quantitative translation of the drug-metabolizing enzyme phenotype derived from *in vitro* studies can be expected to be higher when the NME is also a substrate for nonmetabolic transporter-based clearance mechanisms. The Biopharmaceutics Drug Disposition Classification System (BDDCS) provides a useful framework to guide assessment of the importance of intestinal and hepatic transport as well as enzyme-transporter interplay to the NME's disposition and sensitivity to DDIs, resulting from metabolic and/or transporter inhibition [9,140]. Additionally, knowledge of the BDDCS class of the NME can help guide expectations regarding the level of confidence in IVIVE of metabolic DDI risk based solely on the NME's metabolic phenotype derived from *in vitro* metabolism studies. For instance, the confidence in predictions from *in vitro* metabolism data alone may be relatively high for BDDCS class 1 (i.e., highly soluble and highly permeable/extensively metabolized) NMEs. This is because transporter effects are expected to be minimal in the gut and liver, and it should therefore suffice to consider the impact of intestinal and hepatic drug-metabolizing enzyme inhibition for class 1 NMEs. In contrast, considerations of the contributions of intestinal efflux and hepatic uptake and efflux, as well as enzyme-transporter interplay are particularly important for BDDCS class 2 (i.e., poorly soluble and highly permeable/extensively metabolized) NMEs [141]. Importantly, for BDDCS class 2 NMEs that are substrates of both intestinal drug-metabolizing enzymes (e.g., CYP3A, intestinal UGT isoforms) and efflux transporters (e.g., P-gp), large clinically relevant DDIs can result from coadministration with dual inhibitors of the metabolizing enzyme and efflux transporter (e.g., ritonavir, a potent inhibitor of CYP3A and P-gp). Predicting the clinical correlates of the dynamic interplay of metabolism and transport for BDDCS class 2 drugs requires careful consideration of expectations at each anatomic site of the interaction (e.g., intestinal vs hepatic extraction), given the inverse orientation of P-gp and CYP3A in these organs [142]. Notable progress has been made in the IVIVE and phenotyping of hepatic uptake and efflux clearance through the use of cryopreserved hepatocytes, heterologously expressing cellular models of coupled vectorial transport, and vesicular models for *in vitro* kinetic studies of drug uptake by transporters such as OATP1B1 and OATP1B3 and efflux by transporters such as P-gp, BCRP, and MRP2.

Application of a relative activity factor-based scaling approach has enabled quantification of the contributions of individual organic anion transporting polypeptide (OATP) isoforms to overall hepatic uptake clearance [143–146], with simulation of clinical PK correlates made possible through use of physiologically based PK (PB-PK) models [147–149]. Despite these emerging scientific developments, approaches for estimating the clinical PK correlates of inhibiting individual molecular mechanisms of clearance for drugs cleared via mixed mechanisms (metabolism and transport) remain to be characterized from a standpoint of translational validity. Of note, the examples illustrating the application of the aforementioned methods for transporter identification and phenotyping have been primarily focused on nonmetabolized drugs (primarily BDDCS class 3 drugs) and additional evaluations are necessary to qualify more general applications of the framework for metabolized compounds that may additionally be substrates of active efflux and/or uptake transporters.

3.8.7 Risk Assessment for DDIs with Inducers

An important difference between susceptibility of an NME as an object drug to induction versus inhibition DDI is that when an enzyme is a minor contributor (e.g., $f_{m(CYPi)} < 25\%$) to total clearance of an NME, while the magnitude of an inhibitory DDI will be relatively small even on essentially complete inhibition of the enzyme (< 1.33 -fold), the magnitude of an interaction resulting from strong induction of that enzyme can reach clinically significant magnitudes [123]. Therefore, the relative contribution of inducible enzymes will need to be very small to conclude that the risk for induction DDI is low (e.g., resulting in a $< 25\%$ decrease in NME exposure). For example, it has been shown that even if the contribution of CYP3A to the overall clearance of an object drug is only 25%, the enzyme-inducing anticonvulsants phenytoin and carbamazepine can be expected to produce an ~ 40 – 60% decrease in exposures of the object drug and the strong CYP3A inducer rifampin can be expected to produce an $\sim 65\%$ decrease in the object drug exposure, due to the high intrinsic efficiency of these agents as CYP3A inducers [123].

Additionally, it is important to recognize that induction of multiple drug-metabolizing enzymes and transporters occurs in a pleiotropic manner via common upstream nuclear receptors that regulate the expression of a battery of drug-metabolizing enzyme encoding genes. Therefore, even though the relative contribution of CYP3A per se may be well below 25%, if other PXR-inducible enzymes such as CYPs 2C9 and 2C19 or drug transporters such as P-gp contribute additionally to the overall clearance of the NME, the possibility of clinically significant decreases in exposure following administration of strong PXR agonist inducers such as rifampin cannot be excluded. A recent example illustrating this concept is the interaction between the strong CYP3A inducer rifampin and the antibiotic linezolid, which is not directly metabolized by CYP enzymes, not a substrate of P-gp, and is primarily metabolized by a nonenzymatic chemical oxidation mechanism. In a clinical DDI study, rifampin produced an $\sim 30\%$ reduction in linezolid exposure, with *in silico* simulations demonstrating that an interaction of such magnitude can be explained by a CYP3A contribution to linezolid clearance of $< 10\%$ [150]. Therefore, when determining the need for a clinical DDI study for an NME with a strong inducer (e.g., rifampin), it may be important to consider such studies even if the contribution of inducible clearance pathways is $< 25\%$, because of the possibility that the contribution

of the inducible clearance mechanism can be large enough in the induced state to meaningfully increase the overall clearance of the NME and result in clinically relevant decreases in systemic exposure.

3.9 PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELING AND SIMULATION OF DDIs

The approaches discussed thus far, while useful for initial risk assessment and quantitative predictions of expected interaction magnitude, nevertheless, represent a simplification of the problem of IVIVE of DDIs, as they assume a single constant value of $[I]$, substrate concentrations below the K_m , and do not consider the time-varying concentration of the inhibitor or inducer, or the object drug in the context of typical clinical dosing regimens. These aspects can only be incorporated when the theoretical frameworks for IVIVE of CYP inhibition or induction DDI discussed in the previous sections of this chapter are implemented in the context of a PB-PK model. Use of such a model-based approach allows prediction of not only the fold increase in exposure (AUC) of the object drug but also simulation of the expected PK profile following administration of the metabolic inhibitor or inducer, enabling forecasting of effects on parameters such as peak plasma concentration and half-life. With the availability of automated software to enable such simulations from *in vitro* data the application of full PB-PK model-based methods in drug discovery and development is increasing. The increased use of such model-based approaches is exemplified by many recent publications highlighting the utility of these approaches in the prediction of DDI magnitude [37,38,68,124,139,151,152]. This framework allows simultaneous modeling of object and precipitant drug PK including complexities such as nonlinear PK characteristics, metabolite kinetics and interactions resulting from effects of metabolites in addition to the parent perpetrator agent, and can additionally permit incorporation of multiple mechanisms of interactions (e.g., reversible inhibition, MBI, induction) when dealing with mixed mechanism precipitants with complex properties [38,81,82,153]. In addition to enabling simulation of the typical effect of the metabolic inhibitor on the full PK profile of the object drug, tools such as the Simcyp[®] population simulator allow forecasting of the associated intersubject variability of the DDI in the population because variability in demographic (e.g., body weight), physiological (e.g. liver blood flow), biochemical (e.g., abundance of individual CYP isoforms in the liver, serum albumin concentration), and genetic (e.g., population frequency of CYP2D6 EM vs PM genotypes) parameters are all considered together with drug-specific *in vitro* input parameters (e.g., CYP inhibition K_i , K_m for metabolism of the object drug by individual CYP isoforms) in forecasting outcomes of the DDI in the population [43,154,155]. The use of PB-PK model-based predictions of the outcome of DDIs can be particularly important in guiding the design of clinical DDI studies ahead of conducting them. Simulation studies can be particularly valuable in estimating the required duration of washout between periods of crossover DDI studies as well as guiding the minimum necessary duration of dosing of the precipitant drug to elicit the maximum possible interaction magnitude, both in context of the investigational agent as the object and as the precipitant. A recent example of such an application is in the evaluation of the impact of dose, dosing duration, and dosing frequency of ketoconazole as a strong CYP3A inhibitor on the magnitude of DDI with CYP3A substrates of varying PK characteristics to develop

general recommendations on the optimal dosing regimen of ketoconazole for use as a strong CYP3A inhibitor in clinical DDI studies based on the object drug's characteristics [156]. These approaches can be particularly useful in evaluating whether the magnitude of the interaction can be offset by altering the timing of administration of the object drug and the metabolic inhibitor [157], enabling scientifically guided risk management strategies in later-phase clinical trials, where appropriate, based on the PK properties and clinical dosing regimens of the object and precipitant drugs.

When dealing with the investigational agent as the object drug, physiologically based modeling and simulation can be particularly useful in projecting the impact of DDIs in special patient populations (e.g., patients with renal impairment or genetically distinct subpopulations such as CYP2D6 PMs), where the relative contributions of individual clearance mechanisms to the overall clearance of the investigational agent can be different from those in the general patient population. Consider, for example, a drug that is metabolized by CYP2C19 (major contributor) and CYP3A4 (minor pathway with <20% contributor to total clearance). The effects of CYP3A4 inhibitors can be expected to be minimal and not of clinical significance in patients with functional CYP2C19, whereas this cannot be expected for CYP2C19 PMs where loss of functional activity of CYP2C19 can result in this drug essentially behaving as a "pure" CYP3A substrate, with potentially major risks for clinically important DDIs with strong CYP3A inhibitors. Conducting a DDI study in PMs of CYP2C19 can be operationally challenging, considering the low frequency of the PM genotypes in Western populations. The challenges can be even worse if the investigational agent is a cytotoxic antineoplastic agent that cannot be dosed in healthy volunteers, which would then necessitate the conduct of such a DDI study in a genetically defined special population of cancer patients. Simulations of the expected effect of strong inhibitors (e.g., ketoconazole) on the PK of such a drug in CYP2C19 PMs, using *in vitro* reaction phenotyping data and available clinical PK data in EM versus PM subjects as prior knowledge can represent a powerful approach to forecasting the level of DDI risk in such special populations. Whether such simulations can be solely used in lieu of a dedicated DDI study will, of course, depend on the specific case under consideration and factors such as the population frequency of the special subpopulation, predicted magnitude of the interaction, sensitivity of the predictions to uncertainties in input parameters or key assumptions, as well as the clinical impact of the predicted interaction based on exposure–response understanding of safety of the drug in question. Nevertheless, having the results of such simulations in a drug development setting can guide determination of the timing and design of such special population DDI studies and facilitate scientific discussions with regulatory agencies on the proposed clinical DDI risk assessment and evaluation strategy. Another setting where PB-PK model-based simulations can be helpful is in the forecasting of level of DDI risk via a new route of administration to guide product labeling. An example of such an application is the use of a model-based approach to predicting the magnitude of effect of the strong CYP3A inhibitor ritonavir on the PK of intravenously administered sildenafil, with qualification of the model based on its ability to adequately predict the interaction between oral sildenafil and ritonavir [158]. This analysis provided support for the conclusion that the magnitude of the effect of CYP3A inhibitors on intravenous sildenafil can be expected to be lesser than for oral sildenafil, resulting in the following text in the Clinical Pharmacology section of the USPI: "*Predictions based on a pharmacokinetic model suggest that drug–drug interactions with CYP3A inhibitors will be less than those observed after oral sildenafil administration*" [159].

3.10 DESIGN, ANALYSIS AND INTERPRETATION OF CLINICAL DDI STUDY RESULTS

When designing a clinical DDI study between two drugs, factors requiring consideration include the PK properties of the object and precipitant drugs, the mechanism of the expected interaction (e.g., reversible inhibition, time-dependent inhibition, induction) and wherever possible, the expected magnitude and time course of the interaction (e.g., as predicted from the *in vitro* data and available understanding of the PK properties of the object and precipitant drugs). When evaluating the effect of an NME as an inhibitor or inducer on the PK of a selective probe substrate of an enzyme, the most commonly employed approach is to estimate the effect of multiple-dose administration of the NME on the PK of a single dose of the probe substrate. The NME is typically administered at the highest dose and administration frequency of clinical relevance to estimate the maximum possible magnitude of the interaction. The NME should be dosed until PK steady-state conditions are achieved before administration of the probe substrate. Dosing of the NME should be continued through the period of PK characterization of the probe substrate to maintain the condition of metabolic inhibition or induction. When evaluating the effect of a probe inhibitor or inducer on the PK of an NME, the most commonly applied design involves evaluating the effect of steady-state administration of the selected inhibitor or inducer on the single-dose PK of the NME, provided the multiple-dose PK of the NME are predictable from its single-dose PK profile (i.e., there are no time-dependent nonlinearities in the PK of the object NME).

3.10.1 Common Clinical DDI Study Designs

Many different designs are used for clinical DDI studies [160]. Examples of commonly employed DDI study designs are shown in Fig. 3.8 and will be discussed here. A widely utilized and robust DDI study design is the randomized crossover design (Fig. 3.8a). In this design, subjects are randomized to one of two sequences: a or b. Subjects randomized to sequence a are administered a single test dose of the object drug for PK characterization in period 1 followed by administration of the object drug for PK characterization during multiple-dose administration of the precipitant (at PK steady state of the precipitant) in period 2 to enable assessment of the effect of the precipitant on the object's PK. Dosing of the precipitant drug is continued through the period of PK assessment of the object drug. In sequence b, the order of treatments is reversed such that the single-dose PK of the object drug are evaluated in the setting of steady-state precipitant coadministration in period 1, followed by evaluation of the single-dose PK of the object drug in the absence of the precipitant in period 2. Periods 1 and 2 should be separated by an adequately long washout period that permits complete washout of both the object drug and the precipitant and ensures recalibration to baseline conditions of metabolic activity at the start of the second period. When the precipitant is a reversible CYP inhibitor, the duration of washout can be generally determined easily as five half-lives of the precipitant (and of any known CYP-inhibitory circulating metabolites). In contrast, when the precipitant is a mechanism-based inhibitor or an inducer, the washout period will typically need to be longer than anticipated from PK considerations alone, as the time course of recovery from CYP inactivation or of deinduction, as discussed previously, are dependent not only on the half-life of the precipitant drug but also importantly governed by the biological turnover half-life of

Figure 3.8 Schematic illustration of clinical DDI study designs (O, object drug; P, precipitant drug; PK, pharmacokinetic sampling).

the enzyme that is subject to inactivation or induction. The duration of the washout phase should be adequately long for scientific robustness of the study design. However, in the interest of operational feasibility, the washout period should not be longer than necessary, and optimization is essential. This can be done using physiologically based PK modeling and simulation of DDIs. In some cases, a randomized crossover study design may not be feasible because of a very long half-life of one or both drugs that would make it impractical to incorporate a sufficiently long washout phase between the study periods. In these cases, a fixed-sequence study design (also sometimes referred to as a *one-way crossover design*) is often used where the PK characterization of the object drug alone precedes the PK characterization of the object drug administered with the precipitant (Fig. 3.8b). The duration of the washout period with such a design needs to consider only the half-life of the object drug.

The robustness of the randomized crossover study design over the fixed-sequence design stems from the randomization to one of two sequences such that any potential confounding impact of period and/or sequence effects can be minimized. The risk of a sequence/period effect on PK endpoints is generally low (provided washout is adequate and there is no carryover between periods), given the objective nature of these measurements. Therefore, in most cases, a fixed-sequence study design will be appropriate. In fact, the fixed-sequence design was the most commonly utilized study

design (70% of all studies evaluated) for DDI studies based on an analysis of New Drug Application submissions to the US FDA during the period from December 1995 to November 1996 [160]. However, if the DDI study includes measurement of subjective PD endpoints (e.g., CNS depressant effects using a visual analog scale) in addition to PK endpoints, the randomized crossover design is recommended to minimize potential subjective influences on the study conclusions. This may be applicable, for instance, in DDI studies aimed at evaluating the effect of MDR1 P-gp inhibition on the PK of an NME that is known to be a P-gp substrate. In addition to increasing systemic drug exposure by an increase in the extent of oral absorption (via inhibition of intestinal efflux transport) and/or a decrease in renal and/or biliary clearance, it is possible that P-gp inhibition at the blood–brain barrier may additionally increase CNS drug availability beyond the extent that would be expected based on increases in systemic drug exposure alone. There is currently little clinical evidence to support the clinical significance of such DDIs that may increase human CNS drug distribution via inhibition of P-gp at the blood–brain barrier, although some examples have been reported in experimental clinical pharmacology studies [161,162]. There is little rationale to advocate direct assessment of CNS drug distribution via invasive approaches such as sampling of cerebrospinal fluid in DDI studies evaluating the effects of a P-gp inhibitor (e.g., quinidine) on the PK of a P-gp substrate NME. Nevertheless, if the NME is a P-gp substrate with potential for target or off-target CNS PD effects, it may be useful to include CNS PD and/or safety evaluations in addition to systemic PK measurements in DDI studies evaluating the effect of a P-gp inhibitor. Considering the subjective nature of such endpoints, it would be important to utilize a randomized crossover design instead of a fixed-sequence design in such DDI studies, to permit unbiased evaluation of the PD and/or CNS safety data of special interest. If a randomized crossover design is not feasible (e.g., due to a long half-life of the precipitant drug) and if the potential bias introduced by a fixed-sequence design is to be avoided (e.g., if subjective PD endpoints are being measured), an alternate design that may be used is the randomized parallel group design with a placebo reference (Fig. 3.8c). In this design, subjects are randomized into one of two groups. One group of subjects undergo PK characterization of the object drug alone in period 1 followed by PK characterization of the object drug in the setting of coadministration with the precipitant drug in period 2, and a second group of subjects undergo PK characterization of the object drug alone in period 1 and of the object drug following blinded administration of a placebo in period 2. Such a design provides the ability to separate out the effect of a potential DDI from any confounding period effects.

When evaluating the effect of a probe inhibitor or inducer on the PK of an NME as the object drug, if the PK of the object NME are characterized by time-dependent nonlinear kinetics (e.g., autoinduction or autoinhibition of clearance) and if understanding the effect of enzyme inhibition or induction on the PK of the NME following multiple-dose administration are of primary clinical relevance, the DDI study may need to be designed as a steady-state coadministration study because conclusions from a single-dose DDI study may not be translatable to the clinically relevant setting of multiple-dose administration. As an example, the exposure of single-dose imatinib is increased by the strong CYP3A inhibitor ketoconazole by 40% in a healthy volunteer DDI study [163]. However, a subsequent DDI study in cancer patients in the clinically relevant setting of multiple-dose administration of imatinib failed to reveal an effect of short-term ritonavir (a CYP3A inhibitor that is comparably potent as ketoconazole, with

short-term administration selected to avoid its CYP3A induction effects) on the steady-state exposure of imatinib [164]. Although the mechanism underlying this difference is not entirely clear, it is possible that it may be explained by CYP3A inhibition by imatinib [165] that may translate to an autoinhibition of the CYP3A-mediated component of its oral clearance, thereby resulting in a potentially decreased contribution of CYP3A to steady-state imatinib oral clearance compared to the corresponding contribution following single-dose administration. When designing a multiple-dose coadministration DDI study, the steady-state PK of the NME would need to be characterized following multiple-dose coadministration with the probe inhibitor or inducer and compared to the steady-state PK of the NME administered alone. The multiple-dose coadministration of the probe inhibitor or inducer will need to be performed for a sufficiently long period until attainment and characterization of the new PK steady state of the NME under maximally inhibited or induced conditions of its metabolism. As discussed earlier, optimization of study duration can be achieved using physiologic model-based IVIVEs and comparison of the performance of competing study designs via simulations. One approach to a multiple-dose coadministration DDI study is to utilize a randomized crossover design (similar to that shown in Fig. 3.8b, except that multiple dosing of the NME object drug would be employed instead of single-dose administration). Such a design can be potentially onerous to execute as the study duration will be quite long (especially for drugs with long half-lives), as it would be comprised by the time taken for achievement of PK steady state of the NME alone, the time taken for achievement of PK steady state of the NME in the setting of coadministration of the precipitant drug, and the interperiod washout, which would need to be long enough to ensure return to baseline metabolic conditions and ensure complete washout of both the drugs. Therefore, when multiple-dose coadministration is required for a steady-state DDI evaluation, the use of a fixed-sequence design may be preferred as a simpler alternative (similar to that shown in Fig. 3.8a, except that multiple dosing of the NME object drug would be employed instead of single-dose administration). Even in the setting of a fixed-sequence design, if the half-life of the object drug is long, the total study duration for a steady-state DDI study can be excessive and potentially impractical. In such cases, alternate study designs can be considered, which eliminate the interperiod washout phase. An example of such an alternate design for a multiple-dose coadministration DDI study is shown in Fig. 3.8d. In this design, multiple-dose administration of the object NME is initiated in all subjects and continued until PK steady state is approximately achieved, at which point a PK characterization over the steady-state dosing interval is performed (PK₁). Following completion of this PK assessment of the NME alone, one-half of the subjects continue multiple-dose administration of the object NME alone and another half of the subjects continue multiple-dose administration of the object NME, with coadministration of the probe inhibitor or inducer. The assignment of subjects to the treatment of NME alone versus NME plus probe inhibitor or inducer can be based on randomization that is performed at entry into the study. Both groups of subjects continue their respective multiple-dose study treatments for a prespecified duration that is designed to be adequate to allow achievement of the new PK steady state of the NME when coadministered with the probe inhibitor or inducer. At this point, all subjects undergo PK characterization of the object NME again (PK₂ representing the assessments in subjects coadministered the NME with the probe precipitant; PK₃ representing the assessments in subjects that continued administration of the NME alone). Statistical analysis of the PK₂/PK₁ ratios of systemic exposures

in reference to the PK_3/PK_1 ratios of systemic exposures of the object NME should permit estimation of the magnitude of the interaction.

3.10.2 Statistical Considerations in Design and Analysis of Clinical DDI Studies

A key consideration in the design of clinical PK DDI studies is the determination of an appropriate sample size to enable an informative analysis of the resulting data to guide interpretation of the clinical significance of any observed interaction. DDI studies are generally designed with a sufficient number of subjects that can permit estimation of the magnitude of the interaction with a reasonable level of precision, based on prior knowledge of the variability in PK of the object drug. The operational metric of variability is the within-subject variance in the object drug's PK endpoints (e.g., AUC and C_{max}) for designs where each subject serves as his/her own control and undergoes PK characterization of the object drug alone as well as in the setting of coadministration of the precipitant drug. For less commonly utilized parallel group DDI study designs, the operational metric of variability is the total variance in PK endpoints thereby translating to a larger sample size. The level of precision desired in the estimate of interaction magnitude depends on the broader strategic objective of the DDI study. If the objective is to claim lack of an interaction in proposed labeling and if the exposure–Response relationships for efficacy and safety of the object drug have not been adequately understood, the study would need to be sized to include a sufficient number of subjects for the 90% confidence intervals for the ratio of geometric mean AUC and C_{max} (object plus precipitant in reference to object alone) to be contained within the 80–125% range (default bioequivalence range). However, if the intent is to estimate the magnitude of the interaction with a level of precision that is sufficiently high to allow decisions to be made regarding the potential clinical significance of the interaction to inform risk management strategies and prescribing guidance, sizing the study to show bioequivalence may not be necessary. When dealing with the NME as the object drug, the desired level of precision in estimating the magnitude of the effect of a probe inhibitor or inducer should be ideally based on no-effect boundaries derived from quantitative clinical pharmacologic understanding of the therapeutic index of the object drug [1]. When robust exposure–response relationships for the therapeutic and adverse effects of the NME are available, such understanding provides a powerful framework to prospectively define clinically relevant no-effect boundaries (as opposed to defaulting to the standard bioequivalence criteria) and to interpret the results of the DDI study to guide next steps. PK data from a DDI study are typically analyzed using noncompartmental methods to calculate individual values of PK parameters (e.g., AUC and C_{max}) of the object drug when administered alone and when administered with the precipitant drug. Statistical analysis of PK parameters is generally done using a mixed effects analysis of variance on log-transformed AUC and C_{max} , with estimation of the ratio of geometric mean AUC and C_{max} (object plus precipitant in reference to object alone) and associated 90% confidence intervals. This approach of estimation of interaction magnitude is preferred over hypothesis testing and use of p -values for the assessment of the statistical significance of a DDI, as has been illustrated using representative examples from a review of analyses of DDI studies in New Drug Application submissions to the US FDA during the period from December 1995 to November 1996 [160]. As a hypothetical example, consider the following two scenarios: Study A yielding an estimated ratio of geometric mean AUCs of 89%,

with a 90% confidence interval ranging from 85% to 95% and a p -value of <0.05 ; and Study B yielding an estimated ratio of geometric mean AUCs of 120%, with a 90% confidence interval ranging from 60% to 220% and a p -value $\gg 0.1$. Although Study A revealed a “statistically significant” interaction based on a p -value of <0.05 , this is simply a function of the low within-patient variability in the object drug’s exposure resulting in the ability of the study to demonstrate statistical significance in the small observed decrease in object drug exposure (by 11% on average). However, the 90% confidence interval for the ratio of geometric mean AUC is contained within the 80–125% range, and the observed mean decrease in exposure of 11% would be of no clinical relevance in most cases. Therefore, the conclusion of statistical significance based on a p -value alone is not particularly meaningful or informative to guide next steps in terms of whether the observed interaction requires risk management via dosage increases and/or other precautionary guidance to prescribers. In fact, no further clinical action would typically be necessary for DDIs of this magnitude, and this inference can be reached based on the point estimate of interaction magnitude and the associated 90% confidence interval as a measure of precision in its estimation. In contrast, although the p -value for Study B was $\gg 0.1$, a conclusion of the lack of interaction based solely on the “lack of statistical significance” is not appropriate. Unfortunately, the results of Study B cannot be considered as adequately informative to guide next steps unless exposure–response considerations can be used to justify a wide therapeutic range of the object drug such that decreases in exposure by up to 40% or increases in exposure as large as 2.2-fold would not be of clinical relevance. The poor precision in the estimated interaction magnitude in Study B is likely due to high within-patient variability in the object drug’s exposure. Therefore, although the point estimate of interaction magnitude (1.2-fold increase in AUC) is relatively low, the large uncertainty in its estimation precludes definitive conclusions regarding whether or not there is a clinically meaningful DDI. Again, the p -value is of no value in reaching this conclusion, and it would be inappropriate to use it to suggest the lack of a meaningful interaction. The ability to show statistical significance or the failure to demonstrate statistical significance should not drive interpretation of clinical DDI study results and the use of a confidence interval approach (90% confidence interval about the geometric mean ratio of the AUC and $C_{\max}$ with and without the interacting drug) as opposed to testing for statistical significance is considered as appropriate in the analysis and interpretation of DDI study results. This is reflected in expert opinion articles [166] as well as the Draft FDA and EMA DDI guidance documents [31,39].

3.10.3 Assessment of Clinical Relevance of DDIs

A key strategic objective of clinical DDI studies performed using probe substrates or inhibitors is to utilize the results to evaluate the clinical relevance of potential interactions of the NME with other object drugs with similar clearance mechanisms or precipitant drugs with similar CYP or transporter inhibitory or inductive properties. As discussed previously, use of a sensitive substrate of the target CYP isoform (when investigating the NME as a potential precipitant) or a strong inhibitor or inducer of the contributing CYP isoform (when investigating the NME as the object drug) in the probe DDI study are important to enable assessment of relevance of the interaction with similarly or less sensitive substrates, or with similarly or less potent inhibitors or inducers. This is important because the conduct of each and every possible DDI study

is neither practical nor warranted unless a specific drug combination is of substantial clinical relevance in the target patient population such that specific investigation of a particular interaction will yield medically important information to guide prescribing. For example, consider an NME that is an inhibitor of a drug-metabolizing enzyme, as confirmed in a clinical DDI study evaluating its effects on the PK of a selective and sensitive substrate of the inhibited enzyme. If this NME is expected to be frequently coadministered in clinical practice with a specific object drug with a narrow therapeutic range that is metabolized by the inhibited enzyme, an exact recommended dose reduction or a precise dose titration plan for the object drug of interest may be desirable. This may not be possible to derive based solely on the results of the DDI study conducted with a probe substrate. In such a situation, it can be useful to perform an additional DDI study with the specific object drug of relevance to the intended setting of clinical use of the NME, with the primary objective of contributing to specific prescribing guidance in patients requiring such coadministration.

Some key questions that often need to be considered as part of evaluating the implications of the findings from a clinical DDI study and informing prescribing guidance include:

1. Can the drugs be safely coadministered through appropriate risk management (e.g., safety monitoring, dose reduction) or should use be contraindicated?
2. If the interaction is clinically meaningful, is a dosage adjustment necessary or is it sufficient to advise cautious coadministration with appropriate clinical safety monitoring?
3. If the NME is the object drug, are additional DDI studies needed with other clinically relevant and/or less potent inhibitors or inducers to inform prescribing guidance?
4. If the NME is the precipitant drug, are additional DDI studies needed with other clinically relevant and/or less sensitive substrates of the affected enzyme to inform prescribing guidance?

Modeling and simulation can be particularly helpful in answering these questions with quantitative rigor. The answers to questions 1 and 2 are best developed based on the observed DDI magnitude viewed in context of the clinical safety profile of the drug, exposure–response relationships for efficacy endpoints, and exposure–response relationships for adverse effects. If recommendation of a dose modification of the NME object drug is considered appropriate, integration of DDI study results into population PK/PD models for safety and efficacy of the NME can permit simulation of the performance characteristics of the proposed dose-modification guidelines, an approach analogous to that described for developing dosing recommendations for special populations of patients with impaired renal or hepatic function [167,168]. Consider, for instance, a scenario where the results of a clinical DDI study of an orally administered NME with a strong inhibitor of its metabolism indicate a substantial exposure increase such that a dose reduction of the NME would be necessary to allow coadministration with strong inhibitors. The results of the DDI study can be used to calculate the reduced dose of the NME based on the fold increase in NME exposure estimated in the clinical DDI study. However, in many such instances, only a limited number of dose strengths of the NME may be available and delivery of the calculated reduced dose

may require a unit dose strength that is not available. In such situations, modeling and simulation can represent a valuable approach to test the performance characteristics of alternate dose reduction guidelines that may potentially be supported by the available dose strengths of the NME without having to manufacture and qualify biopharmaceutical performance of lower dose strengths. The key question is whether the proposed dose reduction guideline can be expected to result in a population distribution of NME exposures that would not compromise the benefit/risk balance in patients receiving the strong enzyme inhibitor, which can be addressed using simulations that integrate the DDI study results into the results of population PK/PD models for safety and efficacy endpoints.

Questions 3 and 4 can be addressed using PB-PK modeling and simulation leveraging the available *in vitro* data on both clinically studied and unstudied interactions together with the PK data from the completed clinical DDI studies to simulate the expected outcomes from unstudied interactions. Sensitivity analyses evaluating the impact of unknown or inaccessible model parameters can be particularly helpful in assessing the level of uncertainty in predictions to guide the decision of whether additional clinical DDI studies are of added value.

3.11 EXAMPLES ILLUSTRATING TRANSLATION OF DDI KNOWLEDGE TO PRESCRIBING GUIDANCE

The interpretation of clinical significance of DDIs and the use of clinical DDI study results to guide product labeling, both for the NME as the object drug and for the NME as the precipitant drug, can be better appreciated using some representative examples. If a DDI is characterized by a large clinically significant exposure increase or decrease, and/or a large intersubject variability in interaction magnitude, recommendation of coadministration of the interacting drugs through use of dose modification and/or clinical safety monitoring guidelines may sometimes be difficult. This is because it may be questionable whether a positive benefit/risk balance is preserved when indicating use of the drug in patients receiving such major interacting concomitant medications. This is particularly the case when the object drug has a narrow therapeutic range such that serious unacceptable toxicities can be expected at higher exposures that may be observed as a consequence of DDIs. In such cases, the combination may be contraindicated or alternatively it may be recommended that such concomitant use be avoided. However, if the interaction magnitude is not excessive, it may be possible to utilize the results of controlled clinical DDI studies to provide pharmacokinetically derived dose-modification recommendations in prescribing guidance. These concepts are illustrated using three representative examples (tizanidine, everolimus, and darunavir/ritonavir) that demonstrate the translation of knowledge gained from DDI investigations to the development of risk management guidelines in prescribing guidance.

Example 1: Tizanidine. The centrally acting α_2 -adrenergic agonist tizanidine indicated for the management of spasticity is an ultrasensitive substrate of CYP1A2. When administered with the strong CYP1A2 inhibitor fluvoxamine, a 33-fold mean increase in tizanidine AUC is observed, with a 12-fold mean increase in $C_{\max}$, and a nearly 3-fold prolongation of half-life [169]. Importantly, these PK changes were accompanied by serious clinical consequences of hypotension

(characterized by a mean systolic blood pressure of ~80 mm Hg when coadministered with fluvoxamine) and marked drowsiness and psychomotor impairment reflecting exaggerated PD secondary to the large increase in tizanidine exposure. Additionally, the variability in interaction magnitude was also significant with the 33-fold mean increase in AUC comprised of a range of 14- to 103-fold across individual subjects. In another DDI study that evaluated the effect of another strong CYP1A2 inhibitor ciprofloxacin on tizanidine's clinical pharmacology, a 10-fold mean increase in AUC was observed with clinically significant potentiation of its hypotensive and sedative effects [170]. Considering the large magnitude of these exposure increases and their associated serious clinical consequences that can jeopardize patient safety, it is clear that coadministration of tizanidine with fluvoxamine or ciprofloxacin would not preserve a positive benefit/risk balance for patients. With 2 mg being the lowest available dose strength and 8–12 mg three times a day representing the highest recommended dose of tizanidine, the challenges associated with recommending a dose reduction that would permit safe use of tizanidine in patients requiring fluvoxamine or ciprofloxacin treatment become immediately apparent. Accordingly, the USPI for tizanidine contraindicates its use in patients receiving the strong CYP1A2 inhibitors, fluvoxamine or ciprofloxacin [171]. Additionally, based on *in vitro* studies of the enzymology of tizanidine metabolism that have identified CYP1A2 as the principal determinant of its biotransformation [172] and knowledge of CYP1A2 inhibitory drugs, an extension of DDI risk assessment to other CYP1A2 inhibitors is also possible. Accordingly, the USPI also includes the following statement warning prescribers regarding potential interactions that may be expected with other CYP1A2 inhibitors: “*Because of potential drug interactions, concomitant use of tizanidine with other CYP1A2 inhibitors, such as zileuton, other fluoroquinolones, antiarrhythmics (amiodarone, mexiletine, propafenone, and verapamil), cimetidine, famotidine, oral contraceptives, acyclovir, and ticlopidine should ordinarily be avoided. If their use is clinically necessary, they should be used with caution.*” [171]. This example illustrates the extension of DDI risk assessment to other precipitant drugs based on understanding of the underlying mechanisms and molecular determinants of established interactions.

Example 2: Everolimus. As another example, consider the anticancer drug everolimus, a substrate of CYP3A4 and P-gp. Ketoconazole (strong CYP3A inhibitor and P-gp inhibitor) produced a 15-fold increase in everolimus AUC, and erythromycin and verapamil (moderate CYP3A inhibitors and inhibitors of P-gp) produced 4.4- and 3.5-fold increases in everolimus AUC, respectively [126]. Considering the relatively large magnitude of the observed interaction with ketoconazole, the everolimus USPI recommends that concomitant use of strong CYP3A4 or P-gp inhibitors be avoided [40]. If patients require coadministration with a moderate CYP3A4 inhibitor, the everolimus USPI recommends use with caution at a reduced dose of 2.5 mg/day (one-fourth of the usual recommended dose of 10 mg/day), with a dose increase to 5 mg/day, which may be considered based on patient tolerance [40]. Finally, in a DDI study with the strong CYP3A inducer rifampin, a 64% reduction of everolimus AUC was observed [173]. Accordingly, the USPI recommends that concomitant use of strong CYP3A inducers be avoided and that if such combined use cannot be avoided, a dose increase from 10 to 20 mg/day may be considered

in 5 mg increments [40]. This example illustrates how adequately designed clinical DDI studies can inform the development of pharmacokinetically derived dose-modification guidelines for use in clinical practice when coupled with adequate safety monitoring.

Example 3: Ritonavir-Boosted Darunavir. The examples discussed above represent relatively simple illustrations of the concepts of translating the results of clinical DDI studies to guide prescribing information. There are many such examples across multiple therapeutic areas. Of note, particularly complex dose-modification guidelines are recommended for some antiretroviral agents where clinical use is indicated in the setting of multiagent combination therapy with other antiretroviral agents that have complex inhibitory or inducing effects on CYP enzymes as well as drug transporters. As an example, consider the prescribing information for ritonavir-boosted darunavir that exemplifies the translation to prescribing guidance, of knowledge collectively gained from *in vitro* drug metabolism and DDI studies, understanding of human disposition mechanisms of darunavir as well as coadministered agents, and the results of clinical DDI studies with probe substrates and inhibitors/inducers as well as commonly coadministered drugs. Darunavir is a CYP3A substrate and ritonavir coadministration boosts darunavir exposure by 11-fold due to the strong CYP3A inhibitory effect of ritonavir [174], representing a beneficial and necessary DDI in the context of its clinical use. In fact, to achieve sufficient exposures for antiretroviral therapy, darunavir should only be used with 100-mg BID ritonavir [175]. However, the state of nearly complete deficiency in CYP3A activity produced by regular use of ritonavir in patients receiving treatment with ritonavir-boosted darunavir results in clinically important DDI implications that complicate coadministration of other therapeutic agents that are substrates of CYP3A. In particular, serious safety concerns can be expected when the coadministered agent (i.e., object drug) is highly dependent on CYP3A-mediated metabolism for its clearance and additionally has a narrow therapeutic range. Accordingly, the USPI for darunavir provides a list of such drugs classified by therapeutic class, whose coadministration with darunavir/ritonavir is contraindicated (e.g., alfuzosin, dihydroergotamine, ergonovine, ergotamine, methylegonovine, cisapride, pimozide, oral midazolam, oral triazolam, lovastatin, simvastatin, and sildenafil for treatment of pulmonary arterial hypertension) together with rationale for the contraindication and the potential clinical consequences of coadministration based on knowledge of the safety profile of these object drugs [175]. For other object drugs that are substrates of CYP3A or CYP2D6 (since ritonavir is also an inhibitor of CYP2D6), the USPI offers cautionary guidance and dosage recommendations, where appropriate, based on knowledge of the therapeutic range and safety profile of the object drug and sensitivity to CYP3A or CYP2D6 inhibitory DDIs. Examples of such drugs include but are not limited to CYP3A substrates such as atorvastatin, cyclosporine, and tacrolimus, and CYP2D6 substrates such as risperidone, thioridazine, and metoprolol [175]. Additionally, because of pleiotropic induction of drug-metabolizing enzymes by ritonavir via PXR-mediated mechanisms, exposures of object drugs such as ethinyl estradiol (substrate of CYP3A and phase 2 metabolizing enzymes including UGTs and sulfotransferases) and *S*-warfarin (CYP2C9 substrate) were decreased by 44% and 21%, respectively, in DDI studies performed with oral contraceptives and warfarin, respectively. These findings translate, respectively, to

recommendations for alternate methods of nonhormonal contraception in patients treated with darunavir/ritonavir and monitoring of the international normalized ratio in patients receiving warfarin in combination with darunavir/ritonavir therapy [175]. Finally, with respect to DDI risk assessment for darunavir as the object drug, the USPI contraindicates coadministration with rifampin and St. John's wort based on knowledge of the clinically significant CYP3A inducing effects of these agents that may translate to a decrease in darunavir exposure, which may lead to loss of therapeutic effect and development of resistance [175].

3.12 CONCLUDING REMARKS

DDIs represent an important source of variability in PK that can impact drug response, including both the desired therapeutic effects and the unintended adverse effects. This chapter has provided an overview of the scientific principles, experimental approaches and clinical pharmacologic strategies applied in the investigation of PK DDI characteristics of investigational small molecule drugs during their development, and the application of knowledge gained from such evaluations to contribute to prescribing guidance. This chapter focussed on metabolic DDIs, although it should be noted that the general principles discussed here are also applicable to PK DDIs via nonmetabolic mechanisms (e.g., transporter-mediated DDIs; absorption DDIs via physicochemical or physiologic mechanisms), the investigation of which are equally important. DDI risk assessment and evaluation in drug development needs to consider the complementary scenarios of the NME as a victim or object and as a perpetrator or precipitant. A conceptual framework that illustrates the various considerations around DDI risk assessment and evaluation is provided in Fig. 3.9. The central goal of clinical pharmacologic understanding in drug development is to enable definition of the right dose of the right drug to the right patient populations. To this effect, it is important in drug development to characterize the impact of the various intrinsic and extrinsic sources of PK and PD variability that can influence the therapeutic as well as adverse effects of the drug, thereby altering the overall benefit–risk balance. This is illustrated on the scheme shown on the left panel of Fig. 3.9. DDIs represent an important source of variability, but their effects and clinical relevance will need to be interpreted in the context of other factors that may influence PK (genetic variation in drug-metabolizing enzymes or transporters, effects of food, age, body size, eliminating organ function, etc.) and PDs (PD DDIs, genetic variation in drug target proteins, altered sensitivity due to age or comorbid disease, etc.). Forest plots represent a powerful graphical framework to provide a concise, yet comprehensive, visual illustration of the comparative effects of various intrinsic and extrinsic factors (including the effects of co-administered agents) on the PK exposure parameters of a drug, as applied in recent USPI examples [176]. When utilized in a drug development setting and to guide development of proposed product labeling, such visual frameworks can permit an integrated assessment of the relative magnitude of various DDIs for the NME as the object drug, also in relation to other sources of PK variability including other extrinsic factors as well as intrinsic factors. The right panel of Fig. 3.9 provides a pyramid view of the integrated approach to DDI risk assessment and evaluation in drug development that was focussed on in this chapter. The base of the pyramid reflects the scientific considerations and approaches

Figure 3.9 Integrated approach to strategic integration of DDI risk assessment and evaluation in contemporary drug development.

(experimental and clinical pharmacologic) employed in DDI risk assessment and evaluation that provide the data that serve as the foundation for translation to clinical significance. Of note, knowledge gained from mechanistic *in vitro* drug metabolism and DDI studies and understanding of clearance mechanisms of the object drug, represents critical prior information to enable DDI risk assessment and evaluation of the need for further clinical DDI evaluation. Importantly, understanding of the enzymology of metabolism and disposition of the NME and its effects on the activity and expression of drug-metabolizing enzymes and transporters *in vitro* together with quantitative IVIVE can eliminate the need for unnecessary clinical DDI studies and streamline the clinical DDI evaluation program. Such understanding can permit forecasting of DDI risk with unstudied objects (for NME as precipitant) and unstudied precipitants (for NME as object) based on knowledge of the clearance mechanisms of coadministered agents and knowledge of the effects of the coadministered agents on the clearance mechanisms of the NME, respectively. The quantitative translation of results from *in vitro* DDI studies to predictions of clinical pharmacologic correlates represents an emerging area of research, and this chapter has provided an overview of some of these approaches based on published expert opinion and emerging regulatory guidance (US and EU) in this area. Ultimately, the clinical relevance of PK changes resulting from DDIs will need to be assessed in the context of exposure–response understanding for the efficacy and safety characteristics of the object drug to contribute to product labeling. As is readily apparent from the above discussed integrated approach, DDI risk assessment and evaluation is a highly interdisciplinary science. Strong partnerships and collaborations across drug metabolism scientists, clinical pharmacologists, physicians, pharmacometricians, statisticians, pharmacogeneticists, and regulatory scientists engaged in the cross-functional mission of contemporary drug development are therefore critical to success.

ACKNOWLEDGMENT

I am grateful to Dr. R. Scott Obach for his mentoring, guidance, and collaboration that have been critical to my scientific growth and development at the interface of drug metabolism and clinical pharmacology. I thank him for many scientific discussions during the development of this chapter and for his review and feedback on its content.

4.1 SUMMARY

The failure of lead candidate drugs in clinical trials is often because of the drug's toxicity, related to poor pharmacokinetic (PK) behavior, or the potential to be involved in drug–drug interactions (DDIs) in human patients. The prediction and accurate assessment of clinically relevant DDIs for novel drug candidates represents one of the major tasks of contemporary drug development. Understanding underlying mechanisms of DDIs and obtaining relevant ADME (adsorption, distribution, metabolism, and excretion) characteristics early in drug development helps to improve successful selection of candidate compounds. For more than two decades, information regarding the potential ability of a new drug to participate in clinically relevant dispositional DDIs leading to adverse drug reactions has been required during clinical trials. At present, such requirements include not only listing potential DDIs but also providing detailed information on the molecular mechanisms, enzymes, and molecular and cellular targets involved, as well interactions with influx and efflux drug transporters. The process includes identifying the enzymes responsible for the metabolism of a new pharmaceutical compound, determining mechanisms of transport across cellular membranes and drug transporters

involved, and determining PK parameters that show utility in predicting DDIs that may possibly lead to adverse drug reactions in humans. In this chapter, we focus on details of this process based on analysis of (i) mechanisms leading to clinically significant DDIs, including enzyme- and transporter-mediated interactions, and (ii) currently available analytical tools, including *in vitro* assays and high throughput screening (HTS) technologies and virtual screening, to assess and predict PK-based, clinically relevant interactions in humans. We proceed with the evolution of current approaches to predict DDIs for novel chemical entities and drug candidates in development and conclude the chapter with analysis of modern trends in the field.

4.2 INTRODUCTION TO THE CLINICALLY SIGNIFICANT DRUG-DRUG INTERACTIONS (DDIs)

4.2.1 The Incidence of Clinically Significant DDI

DDIs occur when the pharmacological effects of one drug are altered by the presence of another drug in the plasma. Clinically significant DDIs can lead to adverse reactions, life-threatening toxicity, or diminished drug efficacy in human patients [1]. In some cases, clinically significant DDI related to severe toxicity have led to the withdrawal of drugs from the market [2]. Clinically significant DDI present serious problems in both ambulatory and hospitalized patients that may lead to increased morbidity and mortality and contribute to the increasing cost of treatment. Indeed, it has been estimated that 2–3% of all hospitalized patients experience adverse reactions caused by DDI [3], and global medical reports indicate DDI in all types of hospitalized patients [4,5], with high incidence of DDI-related adverse effects in intensive care [6,7], psychiatric [8], cancer [9], cardiovascular [10], and HIV patients [11], as well as in patients in pediatric wards [12] and nursing homes [13]. Moreover, according to the National Ambulatory Medical Care Survey and the National Hospital and Ambulatory Medical Care Survey, ~4.5 million adverse drug effects related to ambulatory visits occur in the United States each year, the majority of these in outpatient office practices [14]. An overall high incidence and growing cost of treatment of the toxicity related to DDI in all groups of patients presents serious health and economic concerns [7,15,16]. In some cases, DDI may not result in immediate toxic reactions but cause increased patient exposure to suspected human carcinogens, leading to an increased risk of cancer and mortality in these groups of patients, hence contributing to an indirect increase in the cost of medical treatments [17]. In addition, DDI may blunt therapeutic effects of known anticancer treatments [18] or diminish therapeutic effects by preventing prodrug activation [19], thereby negatively affecting therapeutic effectiveness of the medications. A growing proportion of the aging population and the increased number of patients requiring multiple drugs or polypharmacy regimens (e.g., a practice of coadministering of several drugs to treat multiple health ailments simultaneously) have contributed to the increased incidence of DDI [20]. For instance, more than one-third of all patients over the age of 57 take five or more prescribed drugs [21], while the average number of chronic medications prescribed for cardiac patients varies between six and eight drugs [22]. The issue becomes even more pronounced in the elderly, where over 25% of all hospitalizations in geriatric patients over 80 years involve adverse drug reactions related to DDIs as a result of polypharmacy treatment [23], which presents significant a problem affecting over

40% of the geriatric population in the United States [24]. In all groups of patients, the problem of adverse drug reactions and toxicity associated with DDIs is further complicated by growing numbers of available new drugs and medications, available both by prescription and over the counter. The latter group may include, in addition to drugs, nutraceuticals, dietary supplements, and natural health products with a potential to cause drug–food and drug–nutrient interactions [25,26]. All these facts, including growing elderly populations, the increased incidence of polypharmacy, and the growing number of new medications, have contributed a unique challenge for modern drug development programs, which now face the necessity to perform drug efficacy and safety assessments for novel drug candidates in development in consideration not just with their single use, but with their potential coadministration with a whole spectrum of other established and novel therapeutic agents, including herbal products, nutraceutical compounds, and vitamins [27]. Recent clinical evidence has thus prompted the development of the novel screening strategies based on the advanced tools and assays for the evaluation and prediction of possible clinically significant DDIs (potential drug–drug interactions, pDDIs) [28].

4.2.2 The Importance of Preclinical Assessment of DDI Potential

Prediction and possible prevention of adverse reactions and toxicity caused by DDIs present critical issues in modern pharmacotherapy and pharmaceutical drug development and now are included as a part of preclinical assessment of drug safety and toxicity for drug candidates in development [2]. The importance of preclinical assessment of DDIs is highlighted by the regulatory requirement of DDI information to be included as an integral part of risk assessment of therapeutics during drug development (<http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm072101.pdf>). A significant effort has been made by academic institutions and the pharmaceutical industry to characterize and explore underlying mechanisms of adverse drug reactions and *in vivo* toxicity stemming from clinically significant DDIs that alter toxicity or efficacy of the administered drug. Such efforts, combined with a growing knowledge and understanding of molecular mechanisms of DDI-related adverse drug effects and toxicity, have led to a progressive development and advancement of *in vitro* and *in vivo* analytical tools, assays, and methodologies for prediction and preclinical assessment, as well as predictive modeling of such interactions [24,29]. Many of these tools and methods have now become a part of routinely adopted practices for *in vitro* screening aiming for prediction of DDI-related adverse drug reactions in preclinical drug development. Moreover, screening for the ability of a novel drug candidate to cause significant DDI has shifted to earlier stages in a drug development process and become a central part of the pharmaceutical industry's strategy to reduce attrition rate and the overall cost of bringing new drugs to the market [30]. Such a strategy has also prompted development of novel screening platforms as well as spurring advancements of modern technologies including HTS [31], ultrahigh throughput screening (u-HTS), microarrays, and virtual screening [32,33]. The evolution of the current approach to evaluate DDIs at the preclinical stage, together with analysis of available methods, screening platforms, and tools for prediction of clinically significant DDIs, are described in more detail in this chapter.

4.2.3 Common Types and Mechanisms of Clinically Significant DDIs

Drug action includes desirable (therapeutic) and undesirable (toxic) drug effects and is regarded in terms of a therapeutic window for a particular drug and patient. Coadministration of two different drugs can result in increased undesirable drug effects compared to individual drug use and lead to adverse drug reactions and toxicity stemming from clinically significant DDIs. DDIs based on changes in PK or pharmacodynamic (PD) parameters are classified as PK- or PD-based DDIs, respectively. PD-based DDIs are caused by the coadministered drug interference at the target site and are not directly related to changes of drug concentration in the body or plasma. PK-based DDIs arise from changes in PK parameters (e.g., $C_{\max}$ or AUC) and are related to changes in drug or drug metabolite concentration in a body as a result of coadministered drug interference with one of the ADME parameters (Fig. 4.1). Changes in drug concentration or exposure arising from PK-based DDIs that lead to increased plasma drug concentration may vary significantly, from two- to threefold to more than an order of magnitude [34]. Significant changes in the concentration of unchanged drug or drug metabolite may cause severe toxicity and adverse drug reactions and are classified as clinically significant DDIs. Drugs with a narrow therapeutic range (NTR) or low therapeutic index are more likely to be involved in serious drug interactions. In some cases, the serious adverse effects of the drug therapy can be attributed to a change in concentration and rate of production of reactive metabolites, as in case of thiabendazole bioactivation, leading to clinically significant DDIs [35]. Drug interactions that affect PK behavior occur at several sites within the body, including in the gastrointestinal mucosa and the liver and at drug-binding sites on plasma proteins, such as albumin and α 1-acid glycoprotein. These interactions include changes in the rate/extent of absorption as a result of changes in the function of drug transporters, alterations in the metabolism of compounds by way of inhibition or induction of metabolic enzymes, and changes in the plasma concentration of one drug by competition with another for plasma protein binding [36]. The focus of this chapter is on the *in vitro* tools for prediction of the

Figure 4.1 The dependence of AUC ratio on the fraction of dose eliminated by hepatic metabolism (f_m) when $I = 6 \mu\text{g/mL}$ and $K_i = 0.1 \mu\text{g/mL}$.

PK-based DDIs, and specifically on pDDIs arising from inhibition and induction of major drug-metabolizing enzymes (DMEs) and major drug transporters [37]. Detailed information on adverse drug reactions related to changes in drug absorption profile and interactions with multiple classes of drug transporters is presented in the chapter titled *Conjugation, Transport, and Elimination of Drugs in Humans*.

4.2.4 Involvement of Drug-Metabolizing Enzymes in Drug Interactions

Two of the most common mechanisms of PK-related DDIs involve inhibition or induction of the major DMEs, leading to an increased concentration of drug or metabolite in the patient or to a loss of drug efficacy [36]. Several classes of DMEs are involved in the process of drug biotransformation in humans, catalyzing oxidative and conjugative phases of the drug metabolism process. The cytochrome P450s (CYP450s) are the major group of enzymes involved in the oxidative phase (formerly phase I) of drug metabolism in humans. UDP-glucuronosyltransferases (UGTs) are the main superfamily of conjugative drug metabolism (phase II according to a previous classification). In humans, CYP450 and UGTs are two main classes of DMEs that, together with drug transporters, are involved in the majority of PK-based DDIs [34].

The CYP450 superfamily consists of multiple, intracellular membrane-bound DMEs that express broad, often overlapping, substrate specificities among its different members [38]. According to modern nomenclature, 18 families of human CYP450 genes are divided into 43 subfamilies, with 15 human CYP450 primarily involved in xenobiotic metabolism, all of them being from CYP1, CYP2, and CYP3 families [39]. The CYP450 subfamilies 1–3 are responsible for 70–80% of all oxidative metabolism reactions. In fact, up to 90% of their metabolic activity is attributed to only six enzymes, namely, CYP1A2, CYP3A4, CYP2C9, CYP2C19, CYP2D6, and CYP2E1 [40]. All members of the CYP450 subfamilies can be induced (with the exception of CYP2D6) or inhibited by certain drugs. Alterations in CYP450-mediated metabolic pathways can lead to clinically significant DDIs stemming from inhibition or induction of the individual CYP450 enzymes [41]. At present, significant effort by many ADME programs is devoted to identifying compounds that may alter the major CYP450 oxidative pathways causing clinically significant DDIs [42].

It has been well documented that DDIs involving inhibition of major human CYP450 enzymes represent one of the most common mechanisms leading to increased toxicity and adverse drug reactions in humans [34]. Since 1997, the FDA and other regulators have emphasized the importance of documenting the potential for new orally administered drug candidates to be involved in metabolism-based, PK DDIs with coadministered medicines before a candidate reaches first-in-human studies. Many of these interactions have received considerable attention because some successful drugs (e.g., terfenadine, cisapride) caused severe adverse effects when coadministered with certain anti-infectives [43]. Such interactions involved inhibition of the important members the CYP450 superfamily of DMEs. At present, the FDA provides recommendations for classification of the severity of inhibition for major human CYP450 enzymes. According to the FDA guidance, CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 inhibitors are qualified as strong [fivefold increase in area under the plasma concentration–time curve (AUC) of substrates for specific CYP enzymes], moderate (two- to fivefold increase in AUC), and weak (1.25-fold to twofold increase in AUC). In addition, sensitive substrates for a particular CYP450 enzyme

that cause fivefold increase in AUC in the presence of specific CYP450 inhibitors, or substrates with a NTR, are also defined. For NTR substrates, even small increases in exposure levels may lead to serious safety problems. This classification system can be used for selection of substrate or inhibitor drugs to be used in drug interaction studies or for labeling purposes. For instance, if a novel chemical entity is labeled as a “sensitive CYP3A substrate” or an “NTR CYP3A substrate,” there may be a warning in the label regarding a potential drug interaction with strong or moderate CYP3A inhibitors (CDER Drug Development and Drug Interactions Website, <http://www.fda.gov/Drugs/DevelopmentApprov>) [36].

The conjugative phase of drug metabolism includes reactions of glucuronidation, sulfation, methylation, and acetylation, which may either follow the oxidative phase or be independent of oxidative metabolism by CYP450. Reactions of conjugative drug metabolism quantitatively represent the most important pathways involved in drug biotransformation [44]. In conjugative biotransformation, glucuronidation accounts for up to 35% of all conjugative drug metabolism reactions [45] and is catalyzed by members of the UGT superfamily of DMEs. According to modern nomenclature, the UGT superfamily consists of at least 20 human isozymes encoded by two gene families and three subfamilies (UGT1A, UGT2A, and UGT2B) [46]. UGTs catalyze the conjugation of endobiotics such as bilirubin, steroids, and xenobiotics including drugs, pesticides, carcinogens, and phytochemicals with uridine diphosphoglucuronic acid (UDPGA), resulting in the formation of a glucuronide product (metabolite). The resulting glucuronide is more water soluble compared with the parent compound, and this property facilitates faster metabolite elimination. Changes in the glucuronidation rate of a specific compound due to inhibition or induction of the specific UGT enzyme(s) can affect PK parameters for other drugs that are eliminated primarily via a glucuronidation pathway, resulting in important pharmacological consequences leading to potential toxicity and clinically significant DDIs. Clinically significant pDDIs related to inhibition of human UGTs have recently received considerable attention [45,47]. In addition to xenobiotics, UGT-related adverse drug effects have been attributed to drug interactions with endogenous compounds [48], phytochemicals, and nutritional and herbal supplements [49]. In all cases, for new lead compounds eliminated via the glucuronidation pathway, an accurate assessment of the metabolism rates and PK parameters to predict and prevent UGT-related DDIs is recommended [50].

4.3 BIOLOGICAL AND ANALYTICAL TOOLS USED TO INVESTIGATE PHARMACOKINETICS-BASED DDIs

4.3.1 DDIs Related to Competitive and Noncompetitive Inhibition of CYP450s

It is important to remember that if a candidate compound is metabolized by a particular CYP450 enzyme it will inhibit that enzyme to a degree that depends on the “affinity” of the drug for the catalytic site of the enzyme (K_m) and the concentration of the compound under investigation. However, a compound is not necessarily metabolized by a CYP450 enzyme merely because it inhibits that enzyme. An excellent example of this apparent contradiction is quinidine, which is a potent inhibitor of CYP2D6 but is metabolized by other CYP450 enzymes, including CYP3A4 [51].

When they occur, metabolism-based PK interactions involving inhibition can cause a large increase in exposure to one of the drugs administered by acting as an alternate substrate or an inhibitor, which frequently leads to the onset of adverse, instead of therapeutic, effects [52]. This type of interaction most frequently arises from the competition between two compounds for hepatic CYP450. These interactions can also occur via noncompetitive (allosteric) interactions or by time-dependent metabolic inactivation of an enzyme by one of the drugs. Metabolic interactions can also occur in the small intestine. So the purpose of investigating drug candidates as CYP450 inhibitors *in vitro* is to qualitatively predict their potential to change *in vivo* PK behavior. For example, if polymorphically expressed CYP2D6 is inhibited strongly by a candidate compound, the following are factors that must be considered when predicting the possible significance of the inhibition:

- The extent to which the candidate is cleared by CYP2D6
- The potential for saturating the metabolic capacity of CYP2D6 (easier in poor metabolizers than in extensive metabolizers)
- The possibility of administering the candidate drug with other medications that are CYP2D6 substrates
- The PK behavior of the candidate drug (the potential inhibitor)
- The possible magnitude and potential consequences of alterations (typically increases) in the PK behavior of other CYP2D6 substrates, specifically exposure.

The first factor links reaction phenotyping (enzyme identification) and enzyme inhibition studies. For example, *in vivo*, for a given concentration of a potential inhibitor, as the fraction of the coadministered medicine metabolized (f_m) increases, the AUC increases nonlinearly, until at $f_m = 0.99$, the AUC can typically increase by 35-fold [52]. This was the case for terfenadine when it was coadministered with normal doses of ketoconazole [43]. After conducting an extensive analysis of the utility of these enzyme inhibition studies, Obach *et al.* [53,54] concluded that CYP450 *in vitro* inhibition data are valuable in designing clinical drug interaction study strategies and can be used to predict the magnitude of these interactions.

In order to complete a semiquantitative prediction of the effect of a candidate drug on the PK behavior of an index drug, it is important to determine K_i , the inhibition constant, of the candidate compound for each of the major human liver CYP450 enzymes. K_i is an intrinsic inhibition constant that defines the affinity of the test compound (as opposed to the probe substrate) for the enzyme in question. The value of K_i is much more reproducible from one laboratory to another than IC_{50} , which is specific to a given set of experimental conditions. It is also important to determine the free concentration of candidate drug in the plasma (I). At present, the FDA recommends that the ratio I/K_i should be used to qualitatively predict the probability of significant PK interactions. For example, given an index drug with $f_m = 0.70$, if $I/K_i = 0.1$ for the candidate drug, then the AUC ratio will be 3.2. If $f_m = 0.99$ and $I/K_i = 0.1$, the AUC ratio will be 36.5. However, if $I/K_i = 1.0$, the AUC ratio will be ~ 1.6 , and when $I/K_i = 1000$, the AUC ratio would be ~ 3.99 . So, the FDA position on the value of I/K_i in predicting the clinical significance of interactions is that if its value is 10 or more, it is likely that PK interactions will occur and that necessary clinical drug interaction studies need to be planned. As f_m increases, however, the rise in I/K_i will cause greater increases in AUC (Fig. 4.2).

Figure 4.2 The dependence of AUC ratio on the inhibition index (I/K_i) when $f_m = 0.75$.

4.3.2 DDIs Caused by CYP450 Induction

Drug interactions can also result from an increase in the expression of individual DMEs, particularly the hepatic CYP450 enzymes. DDIs caused by induction of CYP450 can impact the efficacy and safety of coadministered drugs. Therefore, it is important to understand the potential of a new compound to cause enzyme induction and how to use *in vitro* induction data to predict potential for DDIs *in vivo*.

The expression of most of the clinically relevant microsomal CYP450 enzymes in human liver are under the control of xenobiotic-activated nuclear receptors and may be induced by exposure to medications, components of food and herbal supplements, and occupational/environmental contaminants. The notable exception to this generalization is CYP2D6. Many drugs currently on the market in the United States are capable of inducing one or more CYP450 enzymes at therapeutic doses. The effect of enzyme induction is to reduce exposure to drugs that are substrates for the enzyme(s) undergoing induction by increasing the metabolic clearance. In this way, an inducer may change the PK behavior of a second drug, or it may increase its own rate of clearance (autoinduction). The resulting diminution of exposure can reduce efficacy or eliminate desired therapeutic effects.

Hepatic microsomal CYP450 induction is subject to important species-related differences [55,56], such that induction studies conducted with nonhuman species can yield misleading results, making accurate human predictions risky. Furthermore, induction studies conducted in nonhuman species tend to be expensive and require a substantial amount of test compound, unless this objective is incorporated into a repeat-dose toxicity study. However, these difficulties have been overcome by the development of robust human hepatocyte culture methods and the general availability of fresh and cryopreserved cells for this purpose [57]. The constitutive expression of CYP450 genes in cultured hepatocytes invariably falls for the first 48–72 h after seeding, regardless of culture conditions. However, the responsiveness of these genes to appropriate

Figure 4.3 A decision tree for CYP450-based drug–drug interaction studies.

inducers is preserved if culture conditions are selected carefully [58–60]. Optimal culture conditions permit the hepatocytes to exhibit near-normal cellular physiology, gene expression, intercellular contacts, and bile canaliculi formation [61]. Thus, primary cultures of human hepatocytes serve as a selective and sensitive model for predicting the induction of CYP450 *in vivo*. General industry guidance and recommendations for the conduction of CYP450-based inhibition and induction studies for new drug candidates in development are summarized in Fig. 4.3.

Enzyme induction may be measured in several ways. After exposure of human hepatocyte cultures to pharmacologically relevant concentrations of test compound, or vehicle, for two to three days, CYP450-specific mRNA and protein are typically measured and compared. Monitoring enzyme activity against CYP450-specific substrates, directly in cultures or in microsomes harvested from cultures, may also be used to detect enzyme induction. In the best case, there is a clear relationship between nominal test compound concentration and the fold increase in CYP450 activity (Fig. 4.4). In this model, α -naphthaflavone, phenobarbital and rifampin are considered potent prototypical human CYP450 inducers, against which the effect of a test compound is compared. For example, typically, naphthaflavone induces the expression of CYP1A2, phenobarbital induces CYP2B6, and rifampin induces CYP3A4 and CYP2C19. Phenobarbital and rifampin are also capable of inducing members of the CYP2C and CYP2E subfamilies. However, there is cross talk between the nuclear receptors that regulate these enzymes, which may result in a pleiotropic response to some inducers [59]. The best example of this is the effect of phenobarbital on liver function and CYP450 induction [62]. In many cases, the demonstration of CYP450 induction *in vitro* provides an explanation for qualitative changes in PK behavior observed in patients receiving the drug in question. Although the human hepatocyte model is sensitive and specific, it does not consistently and accurately predict the magnitude of PK changes *in vivo* because of the multitude of other factors that can alter drug disposition. However, one method has been suggested for quantitatively predicting the effect of CYP450 induction on PK behavior based on results from *in vitro* experiments using cultured human hepatocytes [63]. The resulting *in vitro*–*in vivo* relationship for eight drugs characterized as

Figure 4.4 Typical fold induction in cultured human hepatocytes of CYP1A2 by 25 μM omeprazole, of CYP2B6 by 500 μM phenobarbital, and of CYP2C9, CYP2C19, and CYP3A4 by 10 μM rifampin.

inducers of CYP1A and CYP3A enzymes, and several enzyme-selective substrates suggested that the ratio E_{max}/EC_{50} for induction determined in cultured human hepatocytes correlated moderately well ($r = 0.768$, $p < 0.05$) with the change in intrinsic hepatic clearance calculated from PK data before and after administration of the inducing drug. This represents a respectable prediction, however, imperfect.

More recently, the activation and translocation of the nuclear receptors that control the transcription of these enzymes have been used as indicators of induction [64,65]. These receptors include aryl hydrocarbon receptor (AhR), constitutive androstane receptor (CAR), and pregnane X receptor (PXR). PXR is the most promiscuous of these [66], and it frequently functions as part of a heterodimer with CAR. Once in the nucleus, these xenosensors bind to xenobiotic responsive elements (proximal and distal promoter sequences) on the target genes and cause an increase in transcription. The heterodimerization of these transcription factors is responsible for the cross talk observed in CYP450 induction. Our understanding of the molecular events involved in induction is incomplete, as is the development of a practical method using this phenomenon to predict the magnitude of human liver CYP450 induction and its effect on PK behavior. One reason for this delay is that hepatocyte culture conditions must support the near-normal expression of these nuclear receptors and no consensus yet exists on ideal or optimal culture conditions. For example, the expression of PXR is also under the influence of the glucocorticoid receptor [62].

4.3.3 DDIs Due to Inhibition of Conjugative Drug-Metabolizing Enzymes

Glucuronidation is an important metabolic pathway of the conjugative phase of drug biotransformation. The variety of substances catalyzed by UGTs includes bioflavonoids, carcinogens, environmental pollutants, and many prescribed drugs from all therapeutic classes [67]. In most of the cases, drug glucuronidation results in detoxification of the parent compound and production of the less harmful metabolites, but in some cases it can lead to the production of reactive metabolites, such as in the bioactivation to genotoxic acyl glucuronide metabolites of carboxylic acid drugs capable of damaging cellular DNA via glycation and/or glycooxidation [68]. UGTs also catalyze glucuronidation of many important endobiotic compounds, including bilirubin, steroids, and bile acids [46]. Therefore, xenobiotics and endobiotics that are eliminated primarily via glucuronidation could be affected by changes in the rate of glucuronidation and production of toxic metabolites, resulting in toxicity and adverse drug reactions in patients. The human hepatic UGTs participate in the clearance of ~15% of the top 200 drugs [69]; there are multiple examples of involvement of this class of DMEs in clinically significant DDIs [70,71]. However, DDIs related to inhibition of human UGT enzymes are less characterized compared to DDIs caused by inhibition of major human CYP450 enzymes. In part, it is related to difficulties in obtaining active UGT enzymes in highly purified form for protein crystallography and modeling studies, obstacles in the development of UGT assays for multiple UGT isoforms, insufficient information about potent and specific isoform-specific inhibitors, and clinical importance of UGT polymorphisms [72]. With further advancements of the UGT field, gaps of knowledge related to the role of UGTs in clinically significant DDIs are expected to be filled, as in the case of CYP450s. At present, there are no consensus requirements regarding the assessment or regulation of UGT-related DDIs in clinical studies. However, an accurate assessment of the specific UGT isozyme involvement, rates of metabolism, and potential to cause UGT-related DDIs is now recommended for all new lead compounds eliminated predominantly via the glucuronidation pathway.

4.3.4 DDIs Due to Competition during Absorption or Elimination of Orally Administered Drugs Involving Transporters

Many human tissues, including the small intestine, liver, kidney, and central nervous system, express a wide variety of drug transporters. Drug transporters mediate the transmembrane passage of drugs and can act as potential sites for the interaction of two or more drugs. This interaction can alter PK behavior significantly, similar to the interactions involving DMEs discussed previously. Members of the solute carrier (SLC) class of membrane transporters are typically located on a basolateral membrane of cells (e.g., hepatocyte sinusoidal membrane). The ATP-binding cassette (ABC) transporters are usually found on an apical membrane (e.g., biliary canalicular membrane, duodenal enterocyte membrane, and renal distal tubule membrane) and facilitate transport of a wide variety of exogenous and endogenous substances across cellular membranes against a concentration gradient via ATP hydrolysis. Pharmaceutical compounds that happen to be good substrates for the export transporters may exhibit poor or variable PK behavior, including limited or unpredictable bioavailability and altered elimination. The export transporters may also alter trough plasma drug concentrations and the

disposition of substrates to peripheral tissues and compartments, thereby changing the dose–response relationship and altering therapeutic effects.

Among the SLC superfamily of drug transporters, several members of the organic anion transporting polypeptide (OATP) family play an important role in the determination of the drug PK parameters. Some drugs, such as cyclosporine, may inhibit OATP transporters, therefore causing PK-based DDIs [73].

The multidrug export transporter P-glycoprotein (PGP) (ABC-type drug efflux pumps, e.g., ABCB1 = P-glycoprotein = MDR1), is the most extensively studied member of the ABC transporter family and is an important site for potential transporter-mediated drug interactions [74]. It is present in the small intestine, blood–brain barrier, distal renal tubule, and placenta. Generally, understanding of PGP and the biological and chemical tools with which to study its contribution to drug interaction potential are more advanced compared to other transporters of the ABC and SLC families.

4.3.5 DDIs Mediated by Inhibition and Induction of PGP

Like many of the human hepatic microsomal CYP450 enzymes, the substrate specificity of PGP is very broad, which makes the prediction of PGP-mediated drug interactions from *in vitro* studies quite difficult. Compounds that interact with PGP may be organized into three classes, based on their ability to stimulate the ATPase activity of PGP and whether they are substrates or inhibitors of the transporter [2,52,68,75–78].

New medicinal compounds may be tested to determine if they are PGP substrates or inhibitors by conducting a bidirectional permeability study in monolayers of polarized cells expressing PGP. These include Caco-2 cells, MDR1-transfected Madin–Darby canine kidney cells, and LLC-PK1 and MDR1-transfected LLC-PK1 cells. These experiments include reference substrates that exhibit low to moderate apparent basal-to-apical membrane permeability ($P_{appA-B} = 2\text{--}30 \times 10^{-6}$ cm/s) and a net flux ratio (P_{appB-A}/P_{appA-B}) of at least 2.0 and inhibitors that exhibit low values of K_i or IC_{50} ($>10\text{ }\mu\text{M}$). Examples of acceptable reference substrates with which to compare new compounds include digoxin, loperamide, and vinblastine, and examples of suitable reference inhibitors include cyclosporin A and elacridar [79]. Unfortunately, because multiple efflux transporters may be expressed in model cell systems and some compounds may inhibit multiple transporters, further experiments should be conducted. However, if the efflux ratio of the new compound is greater than 2.0, and two or three known PGP inhibitors significantly reduce the net flux ratio, the compound is likely to be a PGP substrate. If a significant proportion of the efflux activity is not inhibited by reference PGP inhibitors then other efflux transporters may contribute to the efflux activity. Presently, the results described in the latter case are somewhat difficult to interpret, as our understanding of the many other human efflux transporters is quite limited relative to PGP. The results of studies designed to identify new compounds as PGP substrates may be used to design *in vivo* studies for the investigation of PGP interactions. Clinical examples of PGP-mediated drug interactions include the altered PK of digoxin caused by quinidine and the alteration of fexofenadine PK caused by ketoconazole and erythromycin [79]. Clearly, the involvement of drug transporters can have a significant effect on PK behavior [80]. The expression of PGP in the intestinal epithelium is moderated by the same nuclear receptor, PXR that regulates the expression of CYP3A4. Therefore, repeated oral administration of rifampin or St. John's Wort

can result in an increase in the efflux of PGP substrates from the intestinal epithelium, thus changing the PK behavior by reducing the bioavailability of substrate drugs and reducing therapeutic effects. However, structurally, the ligand-binding domains among animal species are quite divergent from each other and from the human PXR. Furthermore, Caco-2 cell monolayers, so useful in estimating intestinal permeability and absorption, are not suitable for this purpose, possibly due to a lack of human PXR activity in this cell line. Alternately, the human cell adenocarcinoma cell LS180/WT and its adriamycin-resistant (LS180/AD) or vinblastine-resistant (LS180/V) sublines may be used to study PGP induction. However, in general, methods for *in vitro* evaluation of PGP induction, and predicting the effect of this phenomenon on PK behavior, are not well established. In addition, it is very difficult to predict the magnitude of the effect that PGP induction will have on PK variables such as bioavailability.

4.3.6 Impact of OATP Transporters on PK Parameters and DDIs

The OATP family of human drug transporters consists of 11 members, of which OATP1B1, 1B3, 2B1, and 1A2 are the most studied for their potential involvement in transporter-mediated DDIs and changes in PK behavior. Among these, the OATP1B1, 1B3, and 2B1 transporters are most frequently expressed in the sinusoidal membrane of hepatocytes, while OATP1A2 is found on the luminal membrane of enterocytes and at the blood–brain barrier, making these all of these organs potential sites for transporter-mediated DDIs.

OATP transporters are involved in the influx transport of both endogenous (e.g., bile acids, conjugated steroids, steroid hormones and their metabolites, and thyroid hormones) and exogenous compounds, including many that are widely prescribed. Several clinically important drugs identified as substrates for these transporters include antibiotics, HMG-CoA inhibitors (statins), antineoplastic agents, and nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., diclofenac, ibuprofen, and lumiracoxib) [73,81,82]. Simultaneous administration of two or more drugs that are substrates of these transporters may alter drug PK parameters, leading to clinically significant DDIs. Common mechanisms of the OATP transporter-mediated DDI may involve inhibiting the specific transporter (e.g., cyclosporine) [83] or altering its expression by the induction [73,84]. Alternative allosteric mechanisms of drug interactions with transporter proteins leading to pDDIs have also been suggested. In addition, OATP1B1 and OATP1B3 may be indirectly involved in the regulation of the expression of several DMEs and transporters mediating transport of ligands for xenobiotic sensing nuclear receptors including PXR and CAR [85]. However, determining the role of a single transporter protein in transporter-mediated DDIs may be challenging because OATP transporters exhibit broad substrate specificity across various members of the family and many of their substrates are also substrates for the CYP450 family of DMEs and PGP [73].

4.3.7 Importance of a Combined Approach

In vitro metabolic studies are now widely accepted as an integral part of drug development, as the results of these studies can be used to establish the need for, and design of, subsequent *in vivo* assessments of potential drug interactions. The evaluation of the potential of a new pharmaceutical compound to be involved in DDIs, and the possible impact of such interactions on its PK behavior, is a necessary part of the

drug development process and regulatory review before market approval [36]. Three fundamental questions require answers. Will other drugs alter the exposure to the new drug? Will this new drug change exposure to other drugs? Will these interactions alter the exposure significantly enough to require dose adjustment of the new drug or other coadministered medicines?

Until two decades ago, the liver was thought to be the only important site of first-pass metabolism for orally administered drugs, but many reports have been published in the interim concerning the important role of the small intestine in influencing the bioavailability of many medications [86]. Although the liver remains an important site of drug metabolism, duodenal and jejunal enterocytes express several enzymes belonging to the CYP450, glutathione-S-transferase [87], and UGT superfamilies [41]. During the past decade, the commercial availability of human biological products (e.g., intestinal and liver microsomal preparations, cryopreserved human hepatocytes, recombinant human DMEs, and cell lines expressing human DMEs, nuclear receptors, and drug transporters) has helped improve predictions of PK behavior and reduced the previous uncertainty associated with using nonhuman analogs of these tools. The use of these has been combined with the development of novel fluorescent and luminescent technologies to assess drug metabolism and inhibition.

As mentioned previously, CYP450 enzymes are important in this context because of their involvement in the elimination of the majority of marketed drugs. Owing to this broad specificity, it is possible that two or more CYP450 enzymes can contribute to the metabolism of a single candidate compound and that many therapeutically unrelated drugs can be metabolized by the same enzyme. When multiple CYP450 enzymes metabolize the same compound, their relative contribution is determined by the ratio $V_{\max}/K_m$, the intrinsic clearance (e.g., oxycodone, CYP2D6, and CYP3A4). When a single CYP450 enzyme determines the rate of elimination of many drugs, they typically exhibit very different affinities and rates of reaction (e.g., serotonin reuptake inhibitors and CYP2D6).

Human *in vitro* systems are commercially available to investigate drug interactions for the purpose of predicting if new compounds could be involved in clinically significant CYP450-related PK interactions, by assisting in the design of meaningful and cost-effective clinical drug interaction studies [52,53]. These tools include characterized human liver microsomes, recombinant human DME and enzyme-selective probe substrates, and inhibitors combined with sensitive and specific bioanalytical assays. Quantitative assays used at this stage may include multiple approaches, such as radiometric assays based on isolation of radiolabeled metabolites [88], high performance liquid chromatographic (HPLC) methods including rapid LC/MS approaches for metabolite analysis [89], and use of fluorogenic CYP450 substrates [34]. Predictions of potential PK-based DDIs are derived from two types of *in vitro* studies. The first is an enzyme inhibition study using pooled human liver microsomes, which are employed to determine if a candidate drug is capable of inhibiting any of the clinically relevant CYP450 enzymes and to what degree. The second is an enzyme induction study, which is conducted in cultured human hepatocytes and is typically used to predict the effect of a test compound on the level of expression, and therefore activity, of clinically relevant CYP450s. Consensus recommendations for appropriate experimental protocols used for CYP450 inhibition studies have been refined and published [36,90,91]. These include recommendations for CYP450-selective probe substrates with which to measure the activity of each enzyme and for potent and selective reference inhibitors with

TABLE 4.1 Human Liver CYP450 Enzymes, Probe Substrates, and Preferred Inhibitors

CYP450	Proportion of Drugs Metabolized (%)	Preferred/Acceptable Reactions	Preferred Inhibitor
CYP1A2	5	Phenacetin O-deethylation or 7-ethoxyresorufin O-deethylation	Furafylline
CYP2B6	25	Bupropion hydroxylation, orfavirenz hydroxylation	Ticlopidine
CYP2C8	1	Taxol 6-hydroxylation or amodiaquine N-deethylation	Quercetin
CYP2C9	11	Tolbutamide methyl-hydroxylation or diclofenac 4'-hydroxylation	Sulfaphenazole
CYP2C19	4	S-mephenytoin 4'-hydroxylation or omeprazole hydroxylation	Ticlopidine
CYP2D6	30	Bufuralol 1'-hydroxylation or dextromethorphan O-demethylation	Quinidine
CYP3A4	52	Testosterone 6 β -hydroxylation and midazolam 1-hydroxylation	Ketoconazole

which to compare the results of the candidate compound and methods for carrying out required experiments (Table 4.1). No such recommendations have yet been proposed for conducting human CYP450 induction studies *in vitro*.

4.4 HIGH THROUGHPUT SCREENING (HTS) AND PREDICTIVE MODELING OF DDIs

4.4.1 HTS Assays for Drug Metabolism: General Approach

Traditionally, ADME studies have been performed with a limited set of compounds late in the development process. The new paradigm in drug discovery includes developing predictive ADME assays amenable to HTS of large numbers of molecules to save both time and money by eliminating undesirable compounds before they reach development [30,92]. For example, incorporation of ADME parameters into the design of combinatorial libraries is now recommended [92]. An example of the successful application of HTS to evaluate and predict possible DDIs is the development of screening platforms for oxidative and conjugative DMEs and drug transporters [72,93]. The advisability of obtaining absorption and metabolism profiles at the earliest stages of drug discovery for the large number of compounds in combinatorial libraries has led to a development of the new generation of assays with higher throughput capabilities along with increased sensitivity and reproducibility. The analytical tools allowing such capability are represented by assays for prediction of DDIs related to inhibition or induction of major human CYP450 enzymes and currently exist in 96-, 384-, 1586-well plates and microarray formats [94]. Performing these assays early in drug development process facilitates elimination of molecules with unwanted metabolic properties and

helps medicinal chemists to produce better clinical candidates with optimized ADME properties [95].

4.4.2 HTS Assays for CYP450

The approach that currently demonstrates the most promise for high throughput inhibitor screens in early discovery is based on the use of fluorogenic substrates, which can be conducted in a low volume homogenous format, requires no postreaction separation steps, and is amenable to automation and further miniaturization, including 384, 1536, and 3456 high density formats and microarray development [94].

Fluorescent HTS methods employ fluorescent P450 substrates that are efficiently metabolized by specific CYP450 isozymes to yield a product with altered fluorescent properties, usually increased fluorescent intensity [96]. Metabolism assessments with fluorogenic substrates are based on the ability of a new compound to inhibit the metabolism of the fluorogenic reporter substrate in the P450 reaction and is dependent on the kinetic parameters of such an interaction [97,98]. The hits from these competitive inhibition screens must be further evaluated to determine whether they are inhibitors or substrates for the indicated isozyme. Several of the fluorescent CYP450 substrates have been applied for the development of 96-well compatible fluorometric assays employing different human CYP450 enzymes [97,98], including polymorphic variants for selected CYP2C9 isoforms [99]. In addition, fluorometric assays in 384-well format for the CYP3A4 and CYP2D6 isozymes have also been developed [100]. Progress in the field led to the resolution of many undesirable features present in early generations of the fluorogenic CYP450 substrates, including their poor aqueous solubility requiring addition of high concentration of the organic solvents, high background fluorescence (e.g., the fluorescence of unmetabolized substrate), and low signal to noise ratios, which originally limited their applications for low volume ultrahigh throughput formats. Recently, highly miniaturized formats for primary screening assays involving several important pharmaceutical targets have been developed [101]. The ability to perform primary screening assays in microwell plates at 1- to 3- μ L volumes has made significant impact on the early stages of drug discovery by accelerating and reducing the cost of the drug discovery process [102]. The u-HTS assays were successfully developed and applied to characterize potency of many drug discovery targets *in vitro*, including pharmaceutically important class of G-protein-coupled receptors (GPCRs) [103]. Later it became apparent that with all the HTS leads being produced and characterized in the u-HTS mode, u-HTS assays of similar speed, precision, and high throughput capabilities for the CYP450 metabolism and inhibition assays involving the principal human CYP450 enzymes CYP3A4, 2D6, 2C9, 2C19, and 1A2 would be beneficial. Following this trend, highly miniaturized CYP450 screening assays were designed to enable facile analysis of CYP450–drug interactions in higher density microplate formats [97,104,105]. In particular, the development of the CYP450 assays in 1536-well plate format became possible following progress in the design and synthesis of novel class of fluorogenic CYP450 substrates characterized by improved solubility, higher metabolic rates, and lower fluorescent background [50,96]. With application of these substrates, IC_{50} values obtained in the 1536-well assays for CYP3A4, 2D6, 2C9, 2C19, and 1A2 demonstrated a high degree of correlation with data obtained in 96-well assays and conventional HPLC-based assays and were used for the study of enzyme-specific DDIs based on CYP450 inhibition. In addition to fluorogenic assays, luminogenic

assays that couple CYP450 enzyme activity to firefly luciferase luminescence were developed in order to screen for CYP450 metabolism and inhibition and related DDIs [106]. These assays, more appropriate for HTS CYP450 screening in early drug discovery, demonstrated improved sensitivity and decreased interference with optical properties of the compounds libraries. Both fluorogenic and luminogenic substrates have also been applied to measure CYP450 induction in cells [106,107], although high throughput (HT) capabilities of such assays in current formats are somewhat limited. Coincidentally, toxicological and pharmacological implications of CYP450 induction remain much less investigated. Recent reports indicate that altered expression of these enzymes may be of clinical significance and could result in increased toxicity because of the accumulation of toxic metabolites, drug side effects, or by altering the therapeutic efficacy of a coadministered drug. Therefore, identifying compounds involved in CYP450 induction, in addition to CYP450 inhibitors, would allow broadening the overall prediction of the potential for CYP450-related toxicities and DDIs. One of the promising opportunities in the field lies in the possibility of a simultaneous assessment of CYP450 inhibition and induction, allowing identification of CYP450 substrates and inducers and enabling in-depth characterization of their interactions with the CYP450 enzymes, including possible toxicity stemming from such interactions [107]. In future, similar approaches can also be used to create easy read-out assays for the assessment of multiple effects of P450 induction and inhibition for all inducible members of the human CYP450 family. Several promising technologies that show good predictability in a field of CYP450 induction and are amenable to miniaturization, automation, and further development in an HTS format include quantitative nuclease protection assay (qNPA) and PXR transactivation screening assay [108].

4.4.3 HTS Assays for UGTs

Until recently, most of the screening for UGT activity, including screening in the HTS format, was directed toward searching for novel isozyme-selective substrates of high affinity and specificity and not for potent UGT inhibitors [50]. The recent discovery of potent UGT inhibitors, such as the isoform-specific inhibitors for UGT2B7 [109] will have a significant impact toward the design of a future strategy for UGT-HTS screening process. As with CYP450s, one of the possible strategies for UGT screening now includes first-tier binding assays to determine all of the potent modulators of UGT binding activity. This may be combined with second-tier functional assays to determine whether a modulator is a substrate or inhibitor of a specific isoform, and additionally to predict potential UGT-mediated DDIs.

Finally, availability of an active UGT isoform in purified format may facilitate the progress of other methods for detection of UGT activity. For example, a screening method based on the quantification of adenine dinucleotides has been introduced for detection of activity of soluble enzymes, such as kinases and nonmembrane bound soluble bacterial glycosyl transferases [110]. Application of this screening technology in combination with the fluorescent probes designed to reduce light scattering effect [111] was successful in assays using purified, soluble protein preparations. However, these technologies are much more difficult to apply to lipid-containing preparations of membrane proteins, such as UGTs, because of the possibility of a compound partitioning into the hydrophobic membrane fraction, thereby causing unforeseen changes in fluorescent properties.

4.4.4 *In Silico* Assessment: Application of Predictive Modeling and Simulations

Over the years, the development of HTS assays for CYP450 was focused on the early identification of potent inhibitors of major CYP450 isoforms, with the likelihood of causing clinically significant DDIs and adverse drug reactions later in the drug development process as a part of the pharmaceutical industry's strategy to reduce the attrition rate in bringing new drugs to the market [100]. Further progress with the CYP450 HTS platform has led to the development of automated u-HTS assays [105] to screen multithousand-member libraries of diverse compounds and to an appearance of cell-based assays to screen for CYP450 induction [107]. Data obtained in all these assays were used for building predictive CYP450 QSAR models and development and validation of *in silico* screening [112]. A multitude of factors contributed to the availability and success of virtual screening platforms, including advancements in expression, cloning, purification, and reconstitution procedures, allowing the production of large quantities of recombinantly produced active CYP450 enzymes used in protein crystallography and modeling studies [113]. Compared to CYP450, enzyme modeling studies and virtual screening for UGT superfamily of DMEs are less advanced. However, ongoing achievements in the analysis of the recently obtained data in UGT-HTS applications for the screening of diverse chemical libraries are expected to facilitate further progress of the field, including advancements in the UGT modeling studies [114,115]. The identification of novel isozyme-selective UGT substrates and inhibitors, as well as the delineation of the role and significance of particular UGT isozymes, may play an important role in the prediction of clinically relevant DDIs. These advances also include *in silico* modeling of the novel UGT substrates and inhibitors [116].

4.4.5 Limitations and Challenges of Current Approaches

One of the shortcomings of the competitive displacement assays is that compound inhibition potency may be dependent on the nature and concentration of the reporter substance used in the reactions [23]. A valuable approach to HTS is based on the use of a mixture of substrates (substrate cocktail) in the microsomal incubations to simultaneously determine the activities of a number of CYP450 isoforms, including CYP1A2, 2A6, 3A4, 2C9, and 2D6 isoforms, has been recently reported [117]. A sensitive, high throughput ultraperformance liquid chromatography/tandem mass spectrometric (UPLC/MS/MS) method for evaluation of CYP450 inhibition has allowed determination of specific CYP450 inhibition related to DDIs with a panel of test compounds and calculation of the IC_{50} values. In both screening platforms, the possibility of ranking a compound's potency based on their apparent IC_{50} or *in vitro* inhibition constants (K_i) values as an initial step is viewed as a valuable approach to select a set of most potent modulators from a large number of compounds in a compound library for further characterization in secondary assays and additional *in vitro*–*in vivo* correlation experiments [118]. Data obtained in HTS assays have powered the development of computational tools and quantitative structure–activity relationship models aiming to develop new classes of drugs with the least potential of clinically significant DDIs. Despite significant progress in modeling, in the current state of the art, there is a need to enhance the accuracy, interpretability, and confidence in the computational models applicable to drug metabolism in the drug discovery process [119].

4.5 ROLE OF GENETIC POLYMORPHISM AND PHARMACOGENETIC CONSIDERATIONS IN PREDICTION OF DDIs

Both UGTs and CYP450 are highly polymorphic enzymes, and certain functional polymorphisms in these families of enzymes are associated with multiple cases of drug toxicity [120]. For carriers of such polymorphic variants of DMEs, alterations in PK parameters leading to DDIs may have an elevated significance. Several members of the CYP450 superfamily have a high incidence of genetic polymorphisms in human populations; DDI related to CYP2D6, CYP2C19, and CYP3A4 polymorphisms have been reported [121]. Among the UGTs, UGT1A1 is a highly polymorphic enzyme. The alteration of PK parameters and DDIs for the carriers of genetic polymorphisms associated with UGT1A1 [96,122] are of particular importance. One of the common polymorphic variants is UGT1A1*28, which is correlated with decreased transcriptional activity and is associated with mild hyperbilirubinemia or Gilbert's syndrome [123]. Recent evidence suggests that individuals with Gilbert's syndrome, who take medications metabolized by glucuronidation, such as some anticancer agents (irinotecan) and acetaminophen, suffer from increased drug toxicity [10]. Several other UGT1A1 polymorphisms (UGT1A1*33, UGT1A1*34, and the -3156G>A variant) have also been linked to impaired metabolism or increased toxicity of anticancer agents [124,125]. DDIs related to UGT genetic polymorphisms may have more pronounced significance in specific segments of clinical populations, including pediatric and geriatric patients. In pediatric patients, a number of cases of UGT-related DDIs leading to adverse drug reactions and toxicity in children, such as chloramphenicol and other antibiotic agents, have been attributed to changes in specific UGT expression during development (UGT ontogeny) [77]. Therefore, assessment of UGT activity is especially significant in pediatric drug therapy to prevent DDIs in pediatric patients. Glucuronidation is also a major drug metabolism pathway for elimination of many prescribed drugs in geriatric patients, and data related to UGT-based DDIs are important for choosing the proper dose and dose schedule and prevention of DDIs common in the elderly [76].

4.6 CONCLUSIONS AND FUTURE PERSPECTIVES

The current state of technology for the prediction of clinically significant DDIs has led to some important innovations as the field continuously evolves. The existing trend to miniaturize drug metabolism assays and extend them to different classes of targets including enzyme polymorphic variants is expected to progress into the future. For example, one of the emerging issues in the development of miniaturization technologies in screening for adverse drug reactions *in vitro* is the appearance of CYP450 microarrays [20,126]. Several groups have developed gel immobilization techniques of CYP450-containing microsomes, with apparently full preservation of enzyme activity. Another example presents the development of a nanoparticle biosensor for CYP3A4 based on label-free localized surface plasmon resonance spectroscopy [127] and ultimate miniaturization achieved by alginate gel microarray representing a 2000-fold scale down from the traditional 96-well plate format [126].

In general, technologies that have led to the progress in miniaturization of HTS-ADME assays are likely to cross over into other areas where testing of biological responses of vast amounts of individual molecules is required. In general, advances

in these areas will result in further reduction in reaction volumes and concentration of reactants and increased assay rates. The key factor here will be the emergence of standardized robotic hardware capable of handling and reading the nanoliter volumes of solutes and advancement of bioinformatics tools for the data manipulation and analysis. Specific examples of such HTS applications have now been described in the area of genotoxicity environmental testing [94].

Further expansion of virtual screening technologies and computational modeling of major ADME parameters and prediction of relevant DDIs is now a growing field [128], and it is expected to continue to grow in the future [129]. A combination of virtual screening and computational modeling with both high throughput and high content screening technologies allows more biologically relevant data to be obtained from such screens. Similar approaches may be developed as an attempt to systemically investigate complex drug effects on multiple aspects of ADME involving inhibition and induction of both oxidative and conjugative DMEs and drug transporters. In the future, such systematic approaches employing all DMEs and transporters could be applied to investigate multiple complex mechanisms, allowing more complete and careful assessment and accurate prediction of clinically relevant DDIs.

5.1 SUMMARY

Knowledge of the human biotransformation pathways is critical for safe and effective dosing of a new molecular entity (NME). Predicting human metabolism begins in the early discovery phase where *in silico* and *in vitro* tools are utilized to predict the extent of metabolism, the site of metabolism, and the metabolites formed. These studies may compare the *in vitro* metabolism across species. As development progresses, additional studies are conducted both *in vitro* and *in vivo*, first in animals and then in humans. *In vitro* studies are conducted most often with human liver microsomes, liver slices, or hepatocytes. These studies focus on determining which metabolites are formed and which enzyme systems are responsible for the metabolism. The *in vitro* studies are also utilized to determine if a compound inhibits or induces CYP450 enzymes. Expressed enzyme systems provide an *in vitro* system enriched in specific CYP450 enzymes. Other tissues such as intestinal microsomes may also be included in some studies.

In vivo studies start with determination of a metabolic profile in plasma and excreta obtained from the animal and first-in-human (FIH) studies followed by administration of a radiolabeled dose of an NME to determine the extent of metabolism and the identity of the metabolites in animals and humans. Various analytical tools such as LC/MS/MS, NMR, and radiochromatography are used to analyze samples from the

in vivo studies. The earlier *in vivo* studies are qualitative, while the later studies are more quantitative. Predictions of human biotransformation pathways are challenging, and no one tool completely predicts the actual *in vivo* metabolism 100% of the time.

5.2 INTRODUCTION

The drug discovery and development process includes many phases, starting with the earliest phase of discovering a target through the registration and approval of the drug with the ultimate goal of treating patients. In the early phases of drug discovery, metabolism data can identify liabilities of a potential drug candidate, whereas later in drug development, determination of the metabolism and disposition of a NME in humans are critical to provide safety and dosing information for the product label. The process to understand the biotransformation of a drug starts early in the discovery phase when *in silico* and *in vitro* methods are utilized and proceeds through development with additional *in vitro* and *in vivo* testing in animals and then humans (Fig. 5.1). Although there is no consensus among pharmaceutical companies on the timing of metabolism studies in humans, it is clear that these studies are a requirement of international regulatory agencies in order to successfully register an NME and are usually desired before the start of phase 3 clinical trials [1,2]. Metabolism is often the major clearance pathway of an NME in humans, and many intrinsic and extrinsic factors such as genotype and coadministered drugs can affect metabolism. In addition, first-pass metabolism that occurs during the absorption process before the NME reaches the systemic circulation can affect the bioavailability. Metabolism can also cause intra- and intersubject variability because of differences in metabolism between occasions and/or individuals, thereby leading to differences in systemic exposure and ultimately in efficacy and/or safety in humans.

Information on the biotransformation pathways in humans is a precursor to many other studies. It is important to assess the potential for alterations in exposure due to either coadministration with other drugs that may inhibit or induce the metabolism of the NME or due to different genotypes and phenotypes. This information is a precursor to the clinical pharmacology plan for an NME, especially regarding the potential for drug–drug interaction studies and the definitive cardiac QT study. In addition, the genotype and phenotype of an individual may affect the degree of metabolism of the NME in that individual compared to others, as many of the enzymes that are responsible for the metabolism of an NME are known to be polymorphic.

Figure 5.1 Approximate timing of *in silico*, *in vitro*, and *in vivo* assessments over the course of drug discovery and development.

In assessing clearance pathways for NMEs, information on what drives the clearance is obtained first (i.e., metabolism, renal excretion, biliary transport). Once the biotransformation pathways are elucidated, *in vitro* studies are conducted to determine the enzymes that catalyze the reaction, especially if the enzymes are thought to be cytochrome P450 (CYP450) enzymes. On the basis of the *in vitro* studies, appropriate *in vivo* studies with known inhibitors and/or inducers of the specific enzymes will be conducted. If metabolites are formed via enzymes with genetic polymorphisms, additional studies from subpopulations possessing various alleles known to affect the metabolizing enzyme capability may be conducted. Since the definitive clinical QT cardiac safety study is to be conducted with a dose that reaches exposure approximating the “worst case scenario,” an understanding of the factors that may lead to increased exposure is required before conducting this safety study. Without knowledge of the biotransformation pathways in humans, a sponsor would not know which drug–drug interaction studies to conduct or which doses or dose adjustments would be needed under various circumstances.

Much has been written on the issue of metabolites in safety testing (MIST) [3–17]. In both FDA and International Committee on Harmonization (ICH) regulations, sponsors are encouraged to conduct *in vivo* metabolism studies in humans as early as feasible [18,19] since the major metabolites found in humans must have been tested for safety in animals. A metabolite is considered a major human metabolite if it is Insert greater than or equal to sign. 10% of the total of all circulating drug related substances including parent [ICH M3(R2)] [14]. For major human metabolites, the circulating concentrations in animals used in the toxicology studies should approach or be significantly greater than the human exposure. If the human metabolite is not found in the animals in sufficient quantities, then it is considered a “unique or disproportionate” human metabolite, and additional safety testing with the specific metabolite may need to be conducted in animals before initiating large-scale clinical trials. However, in the majority of the cases one or more of the animal species will produce the same metabolites as humans, making additional animal testing unnecessary. Additional safety testing can be time consuming, can take multiple forms, and can require that large amounts of the metabolite be synthesized. Thus, the sooner a sponsor can predict the human biotransformation pathways, the sooner safety coverage can be addressed. The toxicity of metabolites, especially “reactive” metabolites of a given NME, can lead to adverse events in clinical trials and ultimately to the cessation of its development [20]. Circulating metabolite data and demonstration of coverage in animals used in nonclinical safety studies are usually required before exposing large numbers of patients to the drug in phase 3 trials [14].

The liver is usually considered the major organ responsible for metabolism of drugs, as it contains the highest amount of drug-metabolizing enzymes, especially the CYP450 enzymes. Over 75% of the top prescribed drugs are metabolized by either the CYP450 enzymes or the uridine glucuronosyltransferases (UGTs) [21]. In addition to the liver, some of the CYP450 enzymes such as CYP3A are present in high concentrations in the gastrointestinal mucosa, where they metabolize drugs as they enter the body and before reaching the systemic circulation [22,23]. Human carboxyesterases (hCE) and UGTs are also in high concentrations in both the liver and gastrointestinal mucosa where hydrolysis and conjugation can occur [24,25]. Additional extrahepatic sites of metabolism include organs such as the lungs, kidneys, and skin. Other organs such as the brain can also be a source of drug-metabolizing enzymes, but these are less well

studied and the enzymes present in the brain contribute more to metabolism of endogenous compounds and less to exogenous compounds [26,27]. Extrahepatic metabolism can affect both absorption and excretion of an NME and, thus, may be an important factor in its biotransformation. The abundance of drug-metabolizing enzymes in various tissues differs among species, and this may add to difficulties in predicting human metabolism from nonclinical matrices. Many of the studies on distribution of drug-metabolizing enzymes have been conducted in animal tissues because of the difficulty in obtaining human tissues other than liver and gastrointestinal mucosa. Prediction of human biotransformation in extrahepatic tissues relies heavily on calculation of total, hepatic, and nonhepatic clearances and *in vitro* studies using tissues or specific enzyme systems known to be predominantly found in an extrahepatic tissue. *In vivo* studies after administration of both an intravenous and an oral dose of a drug can help in assessing the degree of metabolism due to first-pass metabolism in either the gastrointestinal tract or liver.

In this chapter, tools used to predict human biotransformation pathways are discussed, beginning with *in silico* tools followed by *in vitro* tools, and then *in vivo* tools. This chapter explains the appropriate use of *in silico*, *in vitro*, and *in vivo* tools as well as the pros and cons for each tool in the quest for predicting the human biotransformation pathways.

5.3 IN SILICO TOOLS

Elucidating the biotransformation pathways in humans is an integral part of the discovery and development process, and the earlier this information can be obtained, the better equipped scientists are for making decisions and developing strategies for new compounds. In the discovery phase when no human *in vivo* data are possible and the *in vitro* data require synthesis of a large array of compounds and metabolites, an alternate approach is to utilize *in silico* methods to predict the human biotransformation pathways. *In silico* methods are computer-based techniques that attempt to predict the *in vivo* biotransformation pathways using computational experiments, mathematical calculations, and scientific analyses [28–32]. Some programs predict the most likely sites of metabolism in a molecule and the extent of metabolism, while other programs predict both the site of metabolism and the structure of the predicted metabolites. The backbone of these computational approaches is the knowledge base compiled from experimental data generated from previous *in vitro* and *in vivo* studies and includes biotransformation data, docking, and electronic information about the enzymes and substrates [20]. Often the data are mined from the literature, but they can also include proprietary experimental information. A necessary component of the *in silico* model building is computational power to run algorithms in parallel and then to generate results in a user-friendly manner.

Throughout the development of computational metabolism predictions, various approaches have been utilized. These include the quantitative structure–activity relationship (QSAR) or quantitative structure–metabolism relationship (QSMR), pharmacophore models, and rule-based/knowledge-based expert systems [29,31]. The availability of the X-ray structures of several CYP450 enzymes (i.e., CYP3A4, CYP2C9, and CYP2B6), especially with bound substrates, has been instrumental in developing these models. Although X-ray structures for the crystals of enzymes

involved in glucuronidation and sulfation have not been determined, QSAR models have been developed to predict metabolic interactions with these enzymes from limited data compared to that utilized in the CYP-based models. These QSAR models include general chemical features of the enzyme–molecule interaction such as hydrophobic interaction, hydrogen bonding, and ionization ability [29]. The electronic models include additional calculations of ground-state energies based on molecular orbital calculations, but these have been used less frequently than the QSAR models [29].

There are many commercially available computational programs to predict biotransformation pathways. Some predict the metabolite structures, while others only predict the site of metabolism. Some are based on CYP450 reactions alone, while others are capable of predicting both phase I and phase II metabolism. The accuracy of these programs relies on the amount and quality of the knowledge, information, and data constituting their training sets or knowledge base. The more extensive and diverse the training data set with regard to molecular structure and pathways, the higher the expected accuracy in predicting the true *in vivo* biotransformation pathways [30].

Currently, one program that combines QSAR and rules-based approaches, MetaDrug™ (GeneGo), has been developed with a database of human drug metabolism information including over 10,000 xenobiotic reactions, over 1500 enzyme substrates, and over 1000 enzyme inhibitors [29]. This package first predicts the regions of a molecule most likely to undergo metabolism and then the structures of the most likely metabolites. The program allows for over 66 metabolic pathways using a set of rules to predict the metabolite transformations, both phase I and phase II reactions. In a literature article, MetaDrug was reported to have correctly predicted >73% of phase I metabolites for 28 diverse molecules [29]. A program called MetaSite™ (Molecular Discovery) predicts the site of CYP450-mediated phase I metabolism and the structures of the most likely metabolites.

Another program currently available is StarDrop™ (Optibrium), which predicts the most vulnerable sites for metabolism with CYP3A4, CYP2D6, and CYP2C9. These three enzymes account for the majority of CYP450-mediated metabolism *in vivo*. Molecules can be redesigned with this program to overcome the potential for a metabolism drug–drug interaction involving these three enzymes.

In silico metabolism predictive systems have clear utility, especially in the early phases of drug discovery when a large number of molecules, sometimes virtual, need to be rapidly prioritized in the absence of *in vivo* or *in vitro* animal or human data. In general, the *in silico* programs tend to overpredict the true *in vivo* metabolism, generating a much larger list of metabolites than that actually found *in vivo* [29], probably due to the complex physiological interactions that can occur *in vivo* (e.g., distribution), but are difficult to completely model computationally. The prediction of initial pathways appears to be more accurate than the overall metabolism profile, while the complex metabolic pathways that occur sequentially and involve both phase I and phase II metabolism are more difficult to predict with the current *in silico* models. Scientists need to be aware that excessive “false-positive” predictions may lead to exclusion of potential molecules from consideration for development. One should be particularly mindful of this because the pathways in animals and humans may differ and the *in vivo* physiological processes that affect biotransformation of a molecule may not be completely modeled in the current *in silico* predictive programs. As the field of

prediction advances, it is hoped that newer *in silico* tools and models will predict not only likely pathways and metabolites but also their quantity and rate [20].

5.4 IN VITRO TOOLS TO MAKE PREDICTIONS

5.4.1 Background

The study of xenobiotic metabolism began in the mid-nineteenth century [33] using mainly *in vivo* administration of chemicals to animals and humans, followed by collection of the urine to look for evidence of bioconversion. Amazingly, despite the fact that the analytical techniques of the time were very crude, all the major pathways of drug metabolism were elucidated, including oxidation, reduction, hydrolysis, conjugation (with glycine, sulfuric acid, and glucuronic acid), acetylation, and mercapturic acid synthesis. In the first half of the twentieth century, the terms *metabolism* and *biotransformation* were not used with respect to foreign compounds but instead focused on the “fate” of the chemical after some form of conversion in the body [34]. In 1893, the term *detoxication* was used for the first time in recognition of the fact that some urinary metabolites were less toxic than the compound administered *in vivo*, and this term became a synonym for what we know today as *drug metabolism*.

The laboratory techniques to investigate the involvement of the liver in drug metabolism were developed as early as the 1930s, beginning with the implementation of nondestructive liver homogenization procedures in 1936 [35]. The utilization of differential centrifugation techniques to separate liver organelles from homogenates was pioneered in the laboratory of James and Elizabeth Miller [36] in the 1940s and was followed by the groundbreaking work of Julius Axelrod, which localized the subcellular machinery responsible for the bioconversion activity in the liver to what is today known as the *microsome* [37]. Studies on the rat carcinogen dimethylaminoazobenzene (DAB) by Mueller and Miller [36] led to the important discovery that metabolism of DAB by liver homogenates required oxygen and NADPH as the reducing agent. Beginning in the 1950s, Brodie and his group [38] began to elucidate the molecular basis of drug oxidation and conjugation reactions, as documented in his 1958 review, “Enzymatic metabolism of drugs and other foreign compounds.” Without the collective groundbreaking work of these pioneers, we would not have the tools that are today taken for granted by the drug metabolism scientist. An overview of the predictive power of the most common hepatic subcellular fractions, cell-based systems, and recombinant DNA-expressed systems that are used to conduct contemporary *in vitro* metabolism experiments is presented in this section of the chapter.

5.4.2 Microsomes (Tissue Specific)

The differential centrifugation of a liver homogenate enables the isolation of specific organelles from the rest of the liver cells. The first centrifugation that is traditionally done at 9,000 or 10,000 *g* will remove intact cells, nuclei, and mitochondria. The remaining supernatant is informally known as the *S9 fraction*, which contains the cytosol and fragments of the endoplasmic reticulum (ER). The cytosol contains many of the soluble enzymes (such as aldehyde oxidase and glutathione *S*-transferase), whereas

the ER contains the CYP450 enzyme system responsible for a majority of the oxidations that occur in the liver. At 100,000 g, the ER will sediment out of solution into a pellet, which contains the vesiclelike microsomes. After suspension of the pellet in an appropriate solution, enzyme activity remains relatively stable if the microsomal stock solution is stored in a freezer at -70°C .

It should be noted that microsomes can be prepared from any tissue, but liver microsomes are the most commonly isolated because liver contains the highest concentration of CYP450 enzymes, followed by the upper gastrointestinal tract. For many years, individual drug metabolism laboratories prepared their own liver microsomes and assessed the CYP450 activity in each batch; however, human livers were generally more difficult to acquire than livers from the various animal species. Today, there are several vendors that provide microsomal stock solutions with a known protein concentration and quantified CYP450 enzyme activity from a large number of species. Thus, liver microsomes are the most common *in vitro* system used to predict *in vivo* biotransformation of xenobiotics.

Microsomes are used as a drug disposition tool for three main purposes: (case 1) to determine the rate and extent of intrinsic clearance (or metabolism) of a drug substrate, (case 2) to establish the *in vitro* metabolic profile for a drug substrate, and (case 3) to investigate the CYP450 enzyme inhibition potential of a drug. For all three of these cases, the primary goal is to generate *in vitro* data that can be extrapolated to the whole animal (or human) *in vivo* [39].

In case 1, the microsomal protein concentration is standardized (e.g., 0.5 mg/mL) in a phosphate buffer (pH 7.4), and a compound is incubated for a given period of time (e.g., 15 or 30 min). The use of a standardized microsomal protein concentration in every experiment allows the rank ordering of discovery compounds within a chemical series for “microsomal stability” or “microsomal clearance.” Metabolic stability in human liver microsomes can be effectively classified (e.g., low, moderate, high) with respect to the known human metabolism of a cassette of reference drugs chosen to encompass a wide range of susceptibility to phase 1 (oxidative) metabolism [40].

This *in vitro* system is also ideally designed to help the drug metabolism scientist determine the so-called unbound intrinsic clearance of the compound for a given species, as long as the microsomal protein binding of the compound is known [41,42]. The technique is also frequently used to identify compounds that are prone to hepatic first-pass metabolism in one or more species, including humans. As discussed earlier, extensive first-pass metabolism can significantly reduce the bioavailability of a potential drug and information on this potential can be obtained *in vitro* before the conduct of an *in vivo* study. In general, commercially successful drugs with low first-pass metabolism are preferable unless the drugs are designed to be prodrugs, which are intended to undergo an initial metabolic step (such as hydrolysis) to activate the pharmacological moiety or moieties.

In case 2, the microsomal incubation serves as a vehicle to generate one or more metabolites of a given drug substrate, which can be identified using established liquid chromatography with mass spectrometry (LC-MS) techniques. The wealth of information that is generated from these metabolite profiling and metabolite identification studies can be used to make predictions of biotransformation pathways in animals and humans well before any *in vivo* studies can be conducted. These *in vitro* experiments can frequently over- or underpredict the circulating human metabolites identified via the definitive human ADME (absorption, distribution, metabolism, and excretion)

study with radiolabel [11]. These authors have presented data-driven trends gleaned from a survey of drug development programs, which indicated that with more complex metabolism, the less likely were the *in vitro* data to predict the circulating human metabolites. However, in general, the *in vitro* data were suitable at predicting overall clearance pathways including excreted metabolites, but often failed to correctly predict the levels of the metabolites that circulated in human plasma.

Consistent with the ability of the *in vitro* system to establish clearance pathways, pooled human liver microsomes are also commonly used to identify the specific CYP enzyme(s) responsible for generation of an oxidative metabolite that accounts for at least 25% of the total clearance. This type of assessment is known as *CYP reaction phenotyping* and is an expected component of the clinical pharmacology package at an NDA (New Drug Application) submission [43]. The prediction of CYP enzymes associated with major biotransformation pathways for NMEs is particularly important in the risk assessment of drug interactions. There are some examples of commercial drugs that either have been withdrawn or have undergone significant label changes based on a determination that the drug was heavily dependent on a particular CYP pathway. In the older example of terfenadine, the discovery that this drug caused life-threatening cardiac effects was ultimately related to the fact that terfenadine was metabolized almost exclusively via CYP3A and inhibition of this clearance pathway led to the buildup of cardiotoxic concentrations of the parent drug [44]. In the more recent case of clopidogrel, it was eventually determined that the first major step in bioactivation to the active species was dependent on CYP2C19, which is polymorphic and thus may be absent in a subset of the patient population who would not receive the expected benefit of the drug [45]. In both these examples, these discoveries were made after the drugs were already on the market, but it is important to note in both cases that this information could have been predicted by *in vitro* metabolism experiments.

For case 3, liver microsomes are used to elucidate the drug interaction potential of the NME on other drugs [39], as opposed to the previous case where another drug inhibits a metabolic pathway of the NME. In both these situations, the human liver microsomes are used to probe the impact of one drug on the metabolism of another, and this information is critical for the clinical safety assessment of any drug under development. One of the reasons that liver microsomes are an ideal system for this *in vitro* assessment is that enzyme kinetics can be easily determined. Unlike cell-based systems (similar to hepatocytes, discussed below), the microsomes do not contain a cellular membrane and can immediately equilibrate with the drug substrate without necessitating membrane translocation by either passive or active processes.

More recently, the risk of mechanism-based (also known as *time-dependent*) inhibition has become an area of interest for many pharmaceutical sponsors and regulators since the reduction of metabolic activity of a particular CYP450 is often maintained for a substantial amount of time beyond the cessation of the dosing of the inhibitor. In many cases, the drug irreversibly binds to the enzyme, and full activity is not restored until complete turnover of the enzyme. Once again, human liver microsomes serve as an ideal medium for screening time-dependent inhibitors by allowing preincubation of the potential inhibitor with the microsomes in the presence of the NADPH cofactor. Subsequently, the diluted preincubation microsomal mixture is used to evaluate the extent of biotransformation of a known probe substrate (e.g., midazolam); if the residual activity of the preincubation mixture is reduced compared to the control incubation, it indicates that the drug substrate poses a clinical risk for time-dependent

inhibition. Mibefradil (Posicor) is a well-known example of a commercial drug that was withdrawn from the market when it was determined to be a potent time-dependent inhibitor of CYP3A4 and the sponsor realized that “the complexity of such prescribing information would make it too difficult to implement” [46].

Although the liver microsomes are a very useful tool for a wide variety of predictive purposes, there are some limitations to this system. One downside of this system is that it is optimized for oxidative (phase I) metabolism and does not enable a straightforward assessment of conjugative (phase II) metabolic reactions such as glucuronidations or sulfations. There have been modifications to the standard systems by replacing the NADPH cofactor with uridine diphosphate glucuronic acid (UDPGA) along with some surfactants to facilitate bioconversion via UGTs in the microsomes [47]. However, these incubations can be difficult to reproduce and are not ideal to predict phase II metabolic reactions, especially ones that depend on less well-known cofactors. Another limitation of the liver microsomes is that the optimal activity of the various enzyme systems is dependent on maintenance of a certain pH and temperature. For example, the CYP enzymes are optimized for activity at pH 7.4 and 37°C, whereas the flavin monooxygenase (FMO) family, which catalyzes many heteroatom oxidations such as N-oxidation, exhibits optimal activity at pH 6.8 and is easily deactivated above an incubation temperature of 40°C. Nevertheless, the long-term maintenance of drug-metabolizing activity, availability, ability to compare species-specific metabolism, and ease of use have made liver microsomes the tool of choice for the drug metabolism scientist.

5.4.3 Hepatocytes

The hepatocyte is the main cell in the liver, accounting for approximately 70–80% of the liver mass, and it contains the majority of the ER containing the CYP450 enzymes. Hepatocytes can be separated from the liver via collagenase digestion, followed by plating and culturing for immediate use or cryopreservation (freezing at very low temperatures) for later use. Hepatocytes in primary culture do not maintain their viability or metabolic activity beyond 72 h and often require induction with exogenous chemicals to increase enzyme activity to reasonable levels [48], whereas the cryopreserved hepatocytes (also known as *cryocytes*) can be sensitive to damage during cycles of freezing and thawing. Unlike microsomes, which are ubiquitous in most drug metabolism laboratories, hepatocytes were not as easy to acquire and prepare due to the difficulty in obtaining cells in fresh supply from any species other than rats or mice. More recently, vendors have made cryocytes available in a wide variety of species, and this tool has become much more accepted in drug metabolism laboratories.

In the early days of cryocyte usage, acceptance was limited because of concerns about the impact of the freezing on the activity of the drug-metabolizing enzymes or that cryopreserving would skew selection toward a subgroup of hepatocytes that would not be representative of the native drug-metabolizing activity of hepatocytes obtained from primary culture [49]. However, widespread use of these cryocytes has demonstrated that they are reasonably reliable and reproducible. A major advantage of cryocytes over liver microsomes is that they are capable of biotransforming drug substrates via UGT and sulfotransferase (ST) conjugating enzymes and specific cofactors are not required because the cell operates as its own intact drug metabolism “factory.” The hepatocyte also allows sequential reactions (i.e., oxidation followed by glucuronidation) leading to

an ultimate metabolite excreted in either urine or feces. Thus, hepatocytes obtained from a variety of animal species and humans provide a straightforward means of qualitatively comparing phase I and phase II metabolism of a given drug substrate across species and determining whether the animal species are generating similar metabolic profiles as the human system. This assessment is important to enable the drug metabolism scientist and toxicologist to select the appropriate nonrodent species for nonclinical safety assessment on the basis of relevant human biotransformation pathways.

Another useful role of cryopreserved hepatocytes is their suitability to generate rate of drug clearance within the intact cell. These hepatocyte clearance assessments can be used to rank order compounds in a chemical series, and in some cases, may be more predictive than the microsomal clearance assessment discussed above because the hepatocytes will enable competition between phase I and II metabolic pathways, which is expected to be more physiologically predictive than the microsomes alone.

There have been some reports that hepatocytes are an alternative system to evaluate inhibition enzyme kinetics and inhibition potential of an NME [49,50]. However, there is no universal agreement on the utility of this system for this purpose because of the previously discussed limitations of membrane translocation and potential bioaccumulation of the drug inside the cell.

Finally, human hepatocytes are the tool of choice to predict CYP450 induction (for the inducible isoenzymes CYP1A2, 2B6, and 3A) of an NME before any repeat-dose human *in vivo* data are available. Initially, only fresh hepatocytes were used for this purpose because of long-term stability concerns, but availability issues made it difficult to plan ahead for the experiments. Several detailed investigations of cryopreserved hepatocytes have qualified the use of this *in vitro* system to assess enzyme induction potential with reliable results [49,51]. In some cases, enzyme induction can result in overproduction of a particular CYP450 leading to increased metabolism of a coadministered drug metabolized by the enzyme. In other cases, CYP induction can result in decreased exposure of the NME itself (known as *autoinduction*). In both situations, predicting the risk of CYP450 induction mediated by an NME is important information for the clinical pharmacology package required for registration of the drug. The ability to make these predictions using hepatocytes is an important advantage of this *in vitro* system.

5.4.4 Liver Slices

In 1953, Julius Axelrod demonstrated that amphetamine was completely metabolized in a rabbit liver slice without addition of any cofactors [37]. Liver slices were used quite often as a miniature version of the intact liver long before there was an understanding of the molecular basis of drug metabolism. However, it was determined that the rate and extent of drug metabolism was highly dependent on the size and thickness of the individual slices [52]. This observation led to the advent of precision-cut liver slices, which could be standardized through adjustment of the settings on the mechanical slicers that soon after became commercially available. These uniform slices could be maintained viable in culture for 1 to 10 days and enabled optimal exchange of nutrients, waste, and gases.

Before cryopreserved hepatocytes had gained widespread acceptance and were available from commercial sources, precision-cut liver slices were the principal tool used by drug metabolism scientists to predict phase I and II metabolism of an NME [53].

Figure 5.2 (a) LC/MS profile for LY14 from 24-h incubation in human liver slices. (b) Radioprofile for LY14 from human plasma 6 h after an oral dose of 5 mg.

As described above for hepatocytes, the *in vitro* correlation of biotransformation across species was the only opportunity to determine if the animals and humans were generating qualitatively (and perhaps quantitatively) similar metabolic profiles before human *in vivo* data were available. As with any tool, mixed results have been obtained with respect to the predictability of liver slices for *in vivo* metabolism of a given NME. A human liver slice profile for Drug LY14 is shown in Fig. 5.2, along with the radioprofile from human plasma 6 h after an oral dose of 5 mg. These chromatograms illustrate the nice correlation for metabolites M1, M2, and M8 between human liver slice and plasma. Although not shown, the M11 metabolite was found to be significant in human urine, demonstrating the value of *in vitro* systems for prediction of operative metabolic routes. A second example where incubation of an NME with human liver slices was qualitatively (but not quantitatively) predictive of human clinical metabolism has been published [54]. In this case, several *in vitro* and *in vivo* metabolites were generated with a high degree of overlap. However, this example demonstrated that there were also many metabolites generated in the animal liver slices that did not have any clinical relevance at all. Thus, while liver slice profiles can be very useful in providing a baseline for predicting human metabolism, one should not assume that all *in vitro* metabolites will be represented as circulating human metabolites [11].

5.4.5 Expressed Enzyme Systems

Pooled human liver microsomes are the tool of choice to evaluate metabolic turnover, enzyme kinetics, enzyme inhibition, and CYP450 reaction phenotyping. The pooling of different sources of human livers allows for some metabolic diversity to be represented in the incubation mixture. In addition, the use of pooled human liver microsomes for enzyme inhibition experiments enables the assessment of metabolic switching from one metabolic pathway to another when the primary pathway is chemically inhibited

[55]. However, there are occasions when recombinant expressed enzyme systems are useful to determine the individual impact of particular CYP450s on the metabolic clearance of an NME [56]. These commercially available, soluble, purified, recombinant human CYPs are produced in *Escherichia coli* and reconstituted with oxidoreductase, cytochrome *b5*, and the appropriate lipids. When supplemented with NADPH, these specific CYP450 enzymes (e.g., CYP3A4, CYP2D6) are capable of distinguishing which enzyme(s) are responsible for the generation of a particular metabolite.

5.4.6 Intestinal Homogenates

As mentioned earlier, the upper gastrointestinal tract (i.e., duodenum and proximal jejunum) is the organ that exhibits the second highest level of CYP450-mediated metabolism after the liver [57]. First-pass gut metabolism is more prevalent than originally thought and was not well understood until a series of serendipitous events occurred related to cyclosporin drug metabolism. It was discovered that when cyclosporin A was administered with grapefruit juice, the exposure of the immunosuppressant was significantly increased by several fold, resulting in unexpected drug toxicity. This increase in drug exposure initially appeared to result from inhibition of CYP3A-mediated clearance; however, it was not understood how grapefruit juice or any of its components was inhibiting CYP3A-mediated hepatic metabolism. Subsequent studies of grapefruit juice revealed that the furanocoumarins are inhibitors of CYP3A, but this inhibition is manifested locally in the intestine at the gut enterocyte, where the CYP3A expression is maximized [58]. As such, intestinal homogenates have become another *in vitro* tool to investigate extrahepatic CYP3A-mediated metabolism [59] as well as esterase-mediated hydrolysis of various prodrugs [60]. It should be noted, however, that standardization of these preparations can be difficult and more meaningful data regarding extrahepatic metabolism can often be obtained from *in situ* intestinal perfusion experiments in whole animals.

5.5 IN VIVO TOOLS TO MAKE PREDICTIONS—ANIMAL STUDIES

5.5.1 Choice of Species

As discussed previously, early in the drug discovery process *in vitro* studies are conducted to assess the extent of metabolism and to compare the metabolic profiles between animal species and humans. These *in vitro* assessments typically play a critical role in the selection of the rodent and nonrodent species for the toxicity assessment. These predictions are then evaluated to determine whether the *in vivo* profiles are consistent with the *in vitro* data. If the *in vivo* assessments suggest alternate routes of metabolism or species-specific metabolism, the choice of toxicity species may be reevaluated to ensure that anticipated human metabolic routes are covered in the nonclinical species, and thereby the toxicity studies. Ultimately, the definitive metabolism package is conducted using radiolabeled drug and will include metabolism in the relevant animal species used for toxicity testing (generally mouse, rat, and dog or monkey). However, the radiolabeled studies are generally conducted later in drug development and thus are used primarily to assess metabolite coverage and major clearance pathways. These studies occur too late to effectively affect the selection of the animal species to be

used in the initial toxicity studies. No one animal species will routinely predict all the *in vivo* human biotransformation pathways. Sometimes the *in vivo* human metabolism is more similar to the nonrodents (dogs, monkeys), while some other times, the human metabolism is more consistent with rodents (mice, rats).

5.5.2 Studies with Unlabeled Compound

Although *in vitro* assays provide a valuable tool for assessing the metabolic stability of compounds in drug discovery, predicting major metabolic pathways and providing for cross-species comparisons in the selection of the toxicity species, *in vitro* experiments do not always accurately predict the *in vivo* metabolic profile, especially from a quantitative standpoint. Therefore, researchers will examine plasma, urine, and/or bile from nonclinical pharmacokinetic or toxicity studies where animals are dosed with unlabeled drug in an attempt to more thoroughly investigate the operative metabolic pathways before conducting the radiolabeled studies. Such “cold” analyses are the first chance to evaluate the predictive power of the *in vitro* systems. In many cases, these *in vivo* assessments suggest that the major metabolic routes were appropriately captured *in vitro*, thus providing additional confidence around one’s understanding of the extent of metabolism and major clearance pathways (based on urine and/or bile). Not infrequently such *in vivo* assessments suggest more extensive metabolism than predicted by the *in vitro* systems and in many cases suggest additional metabolic pathways not readily predicted by the *in vitro* systems. The more complex the operative metabolic pathways, the more likely that there may be disconnects between the *in vitro* and *in vivo* data (i.e., multiple sequential oxidations, oxidations followed by conjugation, non-CYP450-mediated cleavage reactions, or transformations catalyzed by extrahepatic enzymes). In general, *in vitro* analyses are more effective at predicting clearance pathways than major circulating metabolites, as expected because of all the complexities that contribute to whether a metabolite circulates or is rapidly cleared after its formation [11,61].

The samples from unlabeled studies are typically analyzed using LC/MS/MS techniques. It should be noted that the qualitative identification of metabolites from these early studies is quite reliable, allowing for a reasonably accurate prediction of operative clearance pathways. Quantitative profiling is, however, more challenging, as LC/MS or LC/UV signals do not provide a robust measure of the relative contribution of a metabolite in the absence of a synthetic standard (as relatively small structural modifications can lead to significant changes in the UV absorbance and/or MS ionization of the metabolite relative to parent drug). Therefore, such exploratory assessments can sometimes be misleading in terms of identifying major circulating and/or excreted metabolites, with the possibility of over- or underpredicting the relative contribution of any given metabolite.

High resolution or mass defect filtering (MDF) LC/MS techniques [62–68], as well as noise reduction or isotope-pattern filtering algorithms [69,70], have proven to be valuable in analyzing plasma from unlabeled pharmacokinetic or toxicity studies, as well as early clinical studies. This approach takes advantage of the fact that accurate mass of the parent drug (as well as its anticipated metabolites) can be used as a “fingerprint” to identify drug-related ions. A common trait of all the exact mass filtering algorithms is that they facilitate the extraction of drug-related signals from what is otherwise often a very complex total ion chromatogram, effectively filtering

for metabolites with both anticipated and unanticipated biotransformations. Figure 5.3 illustrates the benefit of MDF for Drug LY15, which was administered as a radio-labeled dose to rats. The MDF chromatogram shows significant correlation with the corresponding radioprofile, whereas most of the larger peaks on the total ion current (TIC) are not drug related. Broader access to more affordable and easy to use high resolution instrumentation have made the analysis of unlabeled samples more effective (and efficient) than with historical nominal mass instrumentation (which relied on less restrictive filtering criteria such as precursor ion scans, neutral loss scans, background subtraction), and thus, this technique is being widely used across the pharmaceutical industry. However, it should be noted that this approach still does not provide quantitative assessments of metabolites in these unlabeled samples.

Exploratory *in vivo* assessments of nonclinical matrices can significantly increase one's understanding of the operative metabolic processes for an NME. Taken together, the *in vitro* data and early *in vivo* nonclinical assessments play a critical role when deciding to bring a molecule forward into drug development, in assessing operative metabolic pathways in animals and thereby predicting human metabolic pathways, and in developing early pharmacogenomic strategies. However, these assessments often miss the mark in terms of predicting *a priori* "major circulating human metabolites." Ultimately, the nonclinical radiolabel metabolism studies will provide the most detailed and accurate assessment of the operative metabolic routes for each animal species. Any decisions regarding major circulating metabolites or metabolic routes that are derived primarily from "cold," exploratory analyses are potentially made at risk.

5.5.3 Studies with Radiolabeled Compound

Definitive data regarding major circulating and/or excreted metabolites and metabolic processes for both the nonclinical species and human will be obtained via the conduct of the corresponding radiolabel studies. The nonclinical studies are typically run at the low end of the toxicology dose range, using the same route of administration as the safety studies. Such studies most commonly use ^{14}C -labeled drug (although the use of a ^3H label is not uncommon, particularly for molecules that are tested earlier in the drug development process or for low dose drugs). Utilization of the radiotracer assists in better defining the operative metabolic processes as well as to obtain the mass balance (the total recovery of administered drug in excreta), the plasma pharmacokinetics of the parent drug and total circulating radioactivity, and the major routes of excretion [71–73].

From a metabolite profiling and identification perspective, radiolabeled drug allows metabolites to be profiled in an effectively quantitative manner (whether via a radio-flow detector, fraction collection and liquid scintillation counting, or solid scintillation plates and a TopCount/MicroBeta counter), allowing for direct comparison of the metabolite exposure relative to the total circulating radioactivity or circulating levels of parent drug in plasma, as well as for the calculation of the percent of dose for excreted metabolites. This enables major circulating metabolites and clearance pathways to be determined in the nonclinical species, including quantification of any direct renal and/or biliary clearance of parent drug. Radiolabeling also enables more complete metabolic profiling, in that most metabolites retain the ^{14}C label, and thus, the radiolabel provides a "flag" for drug-related entities. Figure 5.4 shows radiochromatograms for LY15

Figure 5.3 The LC/MS total ion chromatogram (TIC), mass defect filtered (MDF) chromatogram, and radioisotope chromatogram (RIC) for LY15 in rat excreta.

Figure 5.4 Radioprofiles for plasma, feces, and bile after a radiolabeled oral dose of LY15 to rats.

dosed in rat, with profiles for plasma (2 h), feces (0–24 h), and bile (0–12 h). Radiolabeling enables metabolites to be detected that may not otherwise have been identified in unlabeled samples because of poor extraction from the biological matrices, poor ionization, or unanticipated biotransformations (or mass changes).

Like the unlabeled exploratory analyses, the radiolabeled samples (now typically including the feces as well as the plasma, urine, and/or bile) are again analyzed

using LC/MS/MS techniques. The most common metabolic processes include oxidation, reduction, hydrolytic cleavage, or conjugation reactions; thus, to some extent, many metabolic processes can be anticipated based on the chemical structure of the drug. However, only the radiolabeling studies allow one to more or less quantitatively profile all the relevant biotransformation pathways, whether anticipated by mechanism or mass alteration or not.

As for unlabeled studies, high resolution or “exact mass” LC/MS and MS/MS techniques have proven to be incredibly valuable in assigning metabolic structures as part of the radiolabel package. The exact mass component allows one to more effectively filter for drug-related entities, to assign molecular formulas to the observed metabolites, and to assign the relevant MSⁿ fragmentation. Thus, high resolution techniques enable more efficient and effective identification of the relevant transformations and the sites of modification.

However, even with the advantages obtained using high resolution MS data, assigning an identified transformation to an exact position on an NME is structure dependent, and is often not feasible using MS/MS data alone. For example, if oxidation occurs on an aromatic ring (or ring system), an exact site of transformation often cannot be defined due to limited fragmentation of the ring system, and thus, the transformation must be assigned to a region of the drug molecule. Figure 5.5a shows a partial assignment for metabolite M3, a “+16” metabolite of Drug LY06, where mono-oxidation is assigned to the benzazepinone ring (Figure 5.5b). If further structural detail is required (i.e., if a metabolite is a major circulating metabolite, represents a significant primary clearance pathway, or is pharmacologically or toxicologically active), further identification is often accomplished using NMR analysis.

NMR complements LC/MS/MS in the elucidation (or confirmation) of metabolite structures, as it provides data defining structural connectivity. However, NMR typically requires microgram quantity of material and, thus, is much less sensitive than LC/MS. It also requires metabolites to either be isolated/purified or undergo on-line separation (such as LC-NMR). One-dimensional NMR experiments typically analyze for ¹H, ¹³C, or ¹⁹F resonances and provide information on functional groups based on chemical shifts and/or coupling constants. With Two-dimensional NMR (COSY, TOCSY, NOESY/ROESY, HSQC, HMBC) it is possible to look through bond or through space couplings within a molecule, allowing one to establish molecular connectivity and thus provide for more detailed structural elucidation. Figure 5.5c shows

Figure 5.5 Regional assignments for a “+16” metabolite of LY06 (M3) based on LC/MS/MS analysis with (a) and without (b) the loss of water. (c) The definitive assignment for M3 based on NMR analysis.

the definitive assignment for the “+16” metabolite of Drug LY06, where oxidation is assigned definitively to the benzylic carbon based on NMR analysis of a purified sample.

In addition to providing the definitive metabolite profiles for the nonclinical species, the animal radiolabel data are also used to further refine one’s understanding of the relevant human metabolic processes. If *in vitro* data appear to be predictive of *in vivo* and/or the metabolic profiles are similar across the nonclinical species, one is more likely to expect that they have a reasonable understanding of the relevant human pathways. If the *in vitro* data either significantly over- or underpredict the relevant metabolic processes in the nonclinical species and/or the nonclinical species have quite divergent metabolic profiles, one may feel less confident about the anticipated human pathways.

5.6 IN VIVO HUMAN STUDIES

5.6.1 First-in-Human Studies

Exploratory human analyses provide the first direct assessment of *in vivo* human metabolites, including circulating metabolites and excreted metabolites (or clearance pathways) and thus can provide valuable insight into the relevant metabolic processes. These data may be used to trigger additional assessments, including the development of metabolite assays for pharmacologically active or potentially major circulating metabolites, or enzyme identification studies to characterize the enzyme(s) responsible for “major” clearance pathways. As for the nonclinical studies, qualitative identification of metabolites from these studies is quite reliable; however, quantitative profiling can be challenging.

When significant circulating metabolites are noted on the basis of exploratory analyses, a decision is sometimes made to further assess metabolite levels in additional clinical and/or nonclinical trials. There are various levels of bioanalytical assay rigor that can be employed to assess metabolite exposure. The more rigorous approaches (full Good Laboratory Practices (GLP) validation or a qualified research method (QRM)) require definitive identification of the relevant metabolite(s) and synthesis of a synthetic standard(s). Several journal articles have addressed the topic of methodologies to quantitate metabolites [54,74–79] and when either a qualitative or quantitative strategy is appropriate. In addition, the FDA has established guidelines for validation of assays to quantitate compounds, either parent or metabolites, and other regulatory agencies are also writing such guidelines [80,81].

Since one does not usually have a complete set of synthetic standards going into the unlabeled FIH studies, one is typically limited to qualitative or semiquantitative assessments of metabolite levels. For a semiquantitative assessment in the absence of synthetic standards, spectroscopic methods of detection such as NMR (typically either ^1H or ^{19}F) [74,77,79] or UV–vis absorbance [77] have been used to evaluate metabolite exposure. However, both these methods are rather limited due to the poor sensitivity of these techniques relative to LC/MS, and the possibility of significant spectral shifts between parent drug and metabolite(s) for UV analyses.

To overcome the quantitative limitations inherent in the absence of synthetic standards, a series of radiocalibration techniques have been described recently that allow

one to estimate concentrations of metabolites in “cold” samples [75,78]. These techniques create a “calibration standard” by comparing the radioactive and mass spectrometric (MS) signals obtained from a previously generated radiolabeled metabolite (i.e., a metabolite generated in a radiolabeled animal study and/or *in vitro* incubation), enabling one to estimate levels of the same metabolite in unlabeled samples using the acquired MS signal (and the calibration response factor from the radiolabeled sample). This approach allows one to reasonably estimate circulating metabolite levels in early-phase clinical studies before definitive structural assignments and/or synthetic standards are available, enabling an earlier assessment of metabolite coverage and/or possible gaps.

Exploratory analysis of early, unlabeled clinical samples typically provides an improved understanding of the operative human metabolic processes, including major circulating metabolites and clearance pathways. Figure 5.6 illustrates LC/MS chromatograms for the Drug LY14 on the basis of an exploratory analysis of “cold” human plasma and urine samples. The corresponding liver slice profile and human plasma radioprofile were previously shown in Fig. 5.2. In this case, both *in vitro* and exploratory analyses from an early clinical trial were quite predictive of the final human metabolic pathways. However, in some cases (because of the differences in ionization or unanticipated transformations), the exploratory profile can significantly underpredict (or less frequently overpredict) the contribution of a particular metabolite or metabolic pathway, and thus, such data should be considered preliminary. Any decisions regarding safety coverage or major clearance pathways would require further investigation using a more definitive, quantitative assay.

5.6.2 Radiolabeled Studies

Although researchers often have a reasonably good understanding of the major human metabolic pathways before conducting the human [^{14}C] radiolabel ADME study, there are still often gaps, at a minimum, around the quantitative contribution of both circulating and excreted metabolites. Even with newer approaches and technologies such as the use of radiometric calibrants to estimate metabolite exposure in nonradiolabeled studies and high resolution mass filtering to identify unanticipated metabolites, reliable quantitative data concerning important circulating metabolites result from the [^{14}C] human ADME study. No *in silico*, *in vitro*, or exploratory data can definitively address the questions of *in vivo* metabolism.

The human quantitative metabolite data can only be obtained via a radiolabel human ADME study, and for human metabolites that exceed the 10% of total drug-related exposure threshold, one must demonstrate affirmatively that these circulating metabolites are covered, meaning that circulating levels in one or more of the toxicology species must approach (or exceed) circulating human concentrations. If such coverage cannot be established in this manner, direct safety testing of the “disproportionate human metabolites” may be required.

To establish metabolite safety coverage, direct measurement of metabolite exposure based on the single-dose human [^{14}C] study (administered at a pharmacologically relevant dose) has been compared to exposures assessed in the nonclinical [^{14}C] studies (dosed in the low toxicology dose range). Using this approach, plasma, urine, and feces are profiled using LC/radiodetection (using an in-line flow detector or LC fraction collection with subsequent counting) to generate the corresponding radioprofiles.

Figure 5.6 (a) LC/MS profile from pooled human plasma 2 h after oral dose of LY14 at 5 mg. (b) LC/MS profile from 0 to 24 h human urine after oral dose of LY14 at 5 mg.

LC/MS/MS data are collected either in parallel with or subsequent to the radioprofiling to identify the corresponding metabolites. The resulting radioactive peaks are integrated to yield the percentage of circulating radioactivity for plasma metabolites or the percentage of dose for excreted metabolites. The relative “exposure” to these metabolites can then be assessed across species, using the quantitation derived from the radioprofiles. Direct comparison between the radiolabel studies allows cross-species assessments to be made even without definitive structural assignments (i.e., regional assignments) based on matched retention times and LC/MS/MS data. This approach tends to be very resource sparing relative to an approach requiring a validated assay, which would require metabolite isolation/purification, NMR assignment, synthesis of

a standard, and the generation of a validated assay in order to establish metabolite coverage. It should be noted, however, that such comparisons are typically limited to single-dose pharmacokinetics, which may not represent steady-state exposure if a metabolite accumulates with multiple dosing.

The final version of the FDA guidance [18] suggests that steady-state exposure of drug-related components is a more appropriate means of evaluating disproportionate human metabolites than single-dose exposure, given that most NMEs are likely to be dosed in a chronic or semichronic manner. The ICH guidance [19] appeared to be purposefully vague in this regard; however, recent presentations and publications by FDA representatives suggest that assessing steady-state metabolite exposure is still preferred [14]. As multiple-dose [^{14}C] human studies present both scientific and operational barriers, the majority of pharmaceutical companies appear to be addressing this concern using more exploratory methods such as the direct comparison of MS signals for metabolites after single and multiple doses for subjects within a single clinical trial, or radiocalibration approaches [16,75,78]. A second approach for estimating steady-state parameters would be to model metabolite accumulation based on the single-dose data. This approach has been endorsed in recent publications [14], but it requires significant assumptions in projecting the half-life.

Although it is clear that the [^{14}C] ADME human study is the industry standard to assess metabolic profiles for healthy subjects, there is no general agreement on the ideal timing of these studies relative to the submission of a NDA. That said, these studies can directly affect resourcing requirements and the viability of a drug and ultimately drive much of the product label and thus are an important milestone in the drug development of an NME.

5.6.3 Microtracer Studies and Accelerator Mass Spectrometry

Microtracer studies and accelerator mass spectrometry (AMS) can provide possible advantages when it comes to defining the broader metabolism package by enabling (i) quantitative profiling of circulating metabolites in phase 1 clinical trials; (ii) profiling for NMEs, where a normal radiolabel dose may present exposure concerns (such as drugs with extended half-lives or unfavorable distribution kinetics); and (iii) multiple-dose human ADME [^{14}C] studies.

Historically, AMS has been used for radiocarbon dating and has more recently found a role in biomedical investigations, including human ADME assessments [82–84]. In this regard, AMS is predominantly used for the detection of ^{14}C in a lightly labeled sample (although other isotopes including ^3H have been utilized). In essence, a sample (such as plasma) containing low levels of ^{14}C is combusted to CO_2 , reduced back to graphite, and analyzed by AMS to determine the $^{14}\text{C}/^{12}\text{C}$ ratio, thus, effectively serving as an ultrasensitive radiocounter.

“Microtracer” studies differentiate themselves from the early “microdose” studies, in that the former administer a low dose of radioactivity (typically 100–200 nCi of ^{14}C) in conjunction with a standard dose of unlabeled drug, whereas the latter administer a low total dose of a drug (typically radiolabeled). The microdose studies have historically been used to evaluate the relative clinical pharmacokinetics for a series of potential drug candidates in the so-called phase 0 [85–87]. The microtracer studies, on the other hand, provide data very comparable to the standard human [^{14}C] studies, enabling the evaluation of pharmacokinetics, mass balance, and metabolism at a pharmacologically

relevant dose [76,88–90]. The main advantage compared to a conventional human [^{14}C] ADME study is that nanocurie doses are administered to humans, and thus, this dose is not considered to be “radioactive,” such that conventional nonclinical dosimetry studies are not required to support human dosing. This enables one to obtain quantitative information about circulating metabolites well before the traditional human radiolabel ADME study could be conducted. The primary disadvantages are that AMS analysis is time consuming and expensive, and conventional LC/MS/MS techniques must be conducted in parallel to enable metabolite identification. These studies are being used in an exploratory mode to address human metabolism, and, in particular, major circulating metabolites, as part of the early clinical package, allowing researchers to better understand and more effectively react to any potential MIST issues very early in drug development.

Additionally, the microtracer study enables a repeat-dose human ADME study to be conducted using multiple [^{14}C]-radiolabeled doses. Multiple nanocurie-level doses of [^{14}C]-radiotracer are dosed in parallel with therapeutic doses of unlabeled drug to obtain steady-state levels for both total radioactivity and parent drug [76]. On the basis of the low radiolabeled doses, radioanalysis would typically require the use of AMS to quantitate the radioactivity in plasma and excreta, adding significant cost and analytical complexity to the human ADME study. Although scientifically quite attractive, this approach has not been widely utilized to date by the pharmaceutical industry, with alternate “unlabeled” approaches typically being used to estimate metabolite exposure at steady state. Further evolution of the AMS technique resulting in higher throughput, reduced cost, and the ability to acquire the radioanalysis and LC/MS/MS for metabolite identification in parallel could result in significant uptake of this approach with time.

5.7 CONCLUSIONS

As discussed in this chapter, the tools used to predict human biotransformation pathways evolve during the drug discovery and development process, usually starting with *in silico* and *in vitro* tools and culminating with the *in vivo* studies in humans. No single tool will be adequate for the determination of the overall metabolism in humans, and no single strategy will work 100% of the time. Predictions of human metabolism are challenging due to the complexity and integration of the physiological organs and systems that comprise the human body. *In silico* and *in vitro* systems tend to rely on isolated systems (i.e., liver microsomes, hepatocytes) that provide the best estimate of what may occur *in vivo*. *In silico* tools will become increasingly better as the knowledge base improves, but they are unlikely to completely replace either *in vitro* or *in vivo* testing. The *in vitro* systems have been shown to predict clearance pathways quite well, but they are less accurate in quantitating the extent or amount of *in vivo* metabolites. One article [11] showed that the *in vitro* data were predictive of the circulating human metabolites 41% of the time, underpredictive 35% of the time, and overpredictive 24% of the time. Another publication [61] showed that *in vitro* systems were capable of predicting >70% of the primary metabolites and metabolic pathways but were less reliable in predicting the secondary pathways. The predictability using *in vitro* tools is likely to improve as analytical techniques for isolation of human hepatocytes and generation of recombinant enzymes improve, as well as the instrumentation to quantitate low levels of metabolites improves. Although the degree

of predictability from the *in vitro* data may vary, there is general agreement that an *in vivo* study in humans using radiolabeled drug is ultimately needed to determine the human biotransformation pathways. Improvements in identification and quantitation of metabolites using technological advances in instrumentation will likely make it easier to detect metabolism pathways *in vivo*. In addition, increasing regulatory scrutiny on the safety qualification of the major human metabolites will necessitate more creative approaches to improve success in predicting and providing adequate animal coverage of the most important metabolites. Thus, the prediction of human biotransformation pathways will certainly continue to evolve with future scientific advances.

6.1 SUMMARY

Drug metabolism is generally described in three phases: phase I (mainly oxidation), phase II (conjugation), and phase III (transport/elimination). Phase I metabolism, mediated by cytochrome P450 (CYP450) and other enzymes has been discussed elsewhere in this series. The major function of phase II and phase III drug metabolism is the detoxification and subsequent transport/elimination of drugs and other xenobiotics. Consistent with this function, conjugation generally produces a metabolite that is more polar, larger in molecular weight, and charged at physiological pH; characteristics that make the metabolite more amenable as a substrate for transport proteins for ultimate excretion into the urine or bile. Most phase II conjugates are inactive and nontoxic; however, there are exceptions in which conjugation results in bioactivation or reactive metabolites.

Phase II conjugation reactions involve the attachment of a glucuronide, sulfate, glutathione (GSH), methyl, acetyl, or an amino acid moiety. These reactions are catalyzed by a group of enzymes known as *UDP-glucuronosyltransferase* (UGT), *sulfonfyl transferase* (SULT), *glutathione S-transferase* (GST), *methyl transferase* (MT), *N-acetyltransferase* (NAT), and *acyl CoA ligase/N-acyltransferases*, respectively. Of these conjugation reactions, glucuronidation is the most common, accounting for roughly 35% of all phase II drug metabolism reactions followed by the SULTs (20%), GSTs (15%), and NATs (10%) [1]. In addition to catalyzing drug metabolism, almost all of these conjugating enzymes are also involved in important biosynthetic and biochemical pathways and hence each also has specific endogenous substrates. On the basis of similarities in their amino acid sequences, each enzyme is divided into families (e.g., UGT1, UGT2) and then further divided into subfamilies (e.g., UGT1A1, UGT1A2), which are typically referred to as *isoenzymes* or *isoforms*. The respective isoforms of the phase II conjugating enzymes are expressed to some degree in virtually all human tissues and have broad and overlapping substrate specificity.

Phase III metabolism involves the rapid excretion/elimination of drug metabolites into bile or urine via transporter proteins. Phase II conjugative metabolites are often quite polar and cannot escape cells (e.g., hepatocytes) via passive diffusion. Therefore, ATP-mediated active transport is often required to enable phase II conjugates to cross biological membranes. Hence, transport proteins play a major role in the excretion of drugs and other xenobiotics into bile and urine. Similar to phase I metabolites, phase II metabolites are also often the substrates for phase III metabolism. There are multiple types of transport proteins that modulate the uptake and excretion of drugs and metabolites into and out of cells. The focus of this chapter is on those transporters that are involved in the excretion of drugs and metabolites out of the kidney proximal tubule epithelia into the urine and out of the hepatocyte into the bile. On the basis of similarities in their amino acid sequences, each transporter is divided into one of two families [the ATP-binding cassette (ABC) or the solute carrier (SLC) family] and then further divided into subfamilies [e.g., multidrug resistance transporter (MDR), organic anion transporter (OAT)].

Regulation of the phase II drug-metabolizing and phase III transporter proteins (in addition to phase I drug-metabolizing enzymes (DMEs)) is governed by nuclear receptors (NRs) [pregnane X receptor (PXR), constitutive androstane receptor (CAR), etc.]. Consequently, many of the phase II and III enzymes are inducible. As a result of being inducible along with having substrate specificity overlap and multiple isoforms, a number of the phase II and III DMEs and transporters have been implicated in clinical drug–drug interactions.

The complexity of how NRs, phase I and II metabolizing enzymes, and transport proteins interact and modulate drug metabolism is not fully understood. Historically, the CYP450 enzymes and other phase I DMEs have been more extensively studied than the phase II DMEs and phase III drug transport proteins. In the last decade, research efforts have become more focused on the phase II conjugation enzymes and the phase III transporter proteins. Though much more is currently understood about the functionality, mechanisms, control, and regulation of phase II and phase III metabolism; research in this area continues to evolve and uncover new findings.

6.2 DRUG-CONJUGATING (PHASE II) ENZYMES IN HUMANS

6.2.1 Glucuronosyltransferases

Glucuronidation is catalyzed by a family of enzymes known as *UGTs*. The reaction catalyzed by UGT enzymes involves the conjugation of an acceptor molecule (aglycone) with glucuronic acid. The source of glucuronic acid is a cosubstrate known as *UDP glucuronic acid* (UDPGA). The acceptor molecule functional group is typically an –OH or –OOH although glucuronidation has been reported on –NH and even –CH and –SH functional groups. The first glucuronide conjugate was reported by Erdmann [2] in 1844 in the urine of cows, which were fed mango leaves. Euxanthic acid (the glucuronide conjugate of euxanthone) was isolated after treatment of the urine with acid. In the early 1870s, Jaffe [3] identified the sugar moiety as a carboxylic derivative of glucose. Later that decade, Schmiedeberg and Meyer [4] identified this sugar as glucuronic acid from experiments they conducted in dogs with camphor. Finally in 1953, Dutton and Storey [5,6] identified UDPGA as the necessary cofactor for glucuronidation.¹

The ultimate objective of glucuronidation is to increase the solubility of xenobiotic compounds so that they are more readily excreted into the bile and urine. Many drugs (Table 6.1) are glucuronidated by the UGT enzymes including acetaminophen, codeine, morphine, *S*-naproxen, oxazepam, and zidovudine [9]. Figure 6.1 shows the glucuronidation of zidovudine (AZT) by UGT2B7, which is responsible for ~60–75% (oral dose) of the elimination of this drug [10–12]. Although this example shows direct O-glucuronidation, often, lipophilic phase I oxidation metabolites are subsequently glucuronidated. Relative to CYP450 metabolism, glucuronidation generally occurs more rapidly. For example for the flavonoid galangin, glucuronidation was found to occur 11–31 times faster (depending on the site of glucuronidation) than CYP450-mediated metabolism [13]. Therefore, in cases where a compound must first be oxidized by CYP450s before conjugation, oxidation becomes rate limiting in the clearance of the compound. Consequently, changes in phase I metabolism can impact the extent of glucuronidation. As with most phase II enzymes, UGTs are also capable of biotransformation of important endogenous substrates such as bilirubin, bile acids, steroids, and glycolipids.

The UGTs consist of four families, UGT1, UGT2, UGT3, and UGT8, of which UGT1 and UGT2 are relatively well characterized. The single enzyme in the UGT8 family, hUGT8 plays a key role in the biosynthesis of galactocerebrosides [15]. UGT3, the last UGT family to be discovered, contains two isoforms hUGT3A1 and hUGT3A2 and until recently little data were available for this family of enzymes [16]. Interestingly as pointed out by Meech and Mackenzie [16], UGT3A1 employs *N*-acetylglucosamine as the sugar donor for conjugation and not UDPGA, which is the primary sugar donor for all other UGTs. All UGTs share a common backbone with specific isoforms differing from each other in the *N*-aminotermini of their respective amino acid sequence. To date, around 19 human UGTs have been characterized in humans. Only the two subfamilies, UGT1 and UGT2, are involved in drug glucuronidation. Of these subfamilies, UGT1A1, UGT1A4, UGT1A9, and UGT2B7 represent the major UGT isoforms and together they are involved in ~87% of hepatic UGT metabolism of drugs [17].

¹This brief history of glucuronidation was summarized from Conti *et al.*, and Dutton [7,8].

TABLE 6.1 Individual UGT Enzymes and Drugs Involved in Drug Metabolism

<i>Individual UGT Enzymes Primarily Involved in Drug Metabolism</i>			
UGT1A1	UGT1A6	UGT1A9	UGT2B15
UGT1A3	UGT1A7	UGT1A10	UGT2B17
UGT1A4	UGT1A8	UGT2B7	UGT2B28

The concentration of UDPGA in human liver ranges from 201 to 349 $\mu\text{mol/kg}$ liver [18]. Hence, glucuronidation is a major phase II metabolic pathway in humans and has the largest capacity of any of the phase II clearance systems. Several commonly used therapeutics have been found to inhibit *in vitro* UGT activity. For example, the drugs tacrolimus, cyclosporine, and diclofenac are among the most potent (K_i values range from 0.033 to 7.9 μM) with probenecid, troglitazone, and naproxen being less potent inhibitors (K_i values range from 20 to 172 μM) [14]. The compound 7,7,7-triphenylheptyl-UDP has been reported to be a mechanism-based inhibitor of UGT [19,20].

UGTs are present in liver, lung, skin, intestine, kidney, brain, and other tissues. They are membrane-bound enzymes with a molecular weight in the range of 50–60 kDa and are located in the endoplasmic reticulum of the cell [21–26]. Unlike the CYP450 enzymes, which have their active sites facing the cytosol, the active site of UGTs face the luminal side of the ER [27]. Hence, UGT conjugation occurs within the ER as opposed to the cytosol [28]. Interestingly, β -glucuronidase is also located in the ER and along with the UGTs may be involved in the futile cycling of hormone and other conjugates within the cell [29]. The first three-dimensional structural information for a mammalian UGT just recently became available with the characterization of the crystal structure of human UGT2B7 C-terminal end [30].

The more common UGT polymorphisms are those associated with the UGT1A1, UGT1A6, and UGT2B7 isoforms [31]. Of these three isoforms, the most prevalent polymorphisms impacting drug metabolism are those involving UGT1A1. Hereditary diseases such as Gilbert's and Crigler–Najjar syndromes occur as a result of UGT1A1 polymorphism and compromise the ability of individuals afflicted with this condition to properly metabolize bilirubin as well as drugs metabolized by UGT1A1 [32]. Both diseases are characterized by hyperbilirubinemia, which is caused by the buildup of bilirubin levels in the blood. Hyperbilirubinemia in Gilbert's syndrome results in only minor jaundice, while in Crigler–Najjar, bilirubin can reach lethal levels unless subjects undergo phototherapy [33]. Crigler–Najjar syndrome is a rare disease (~ 0.6 per million live births or only a few hundred world wide) and is characterized as two types [34]. Type I is more severe as subjects have no expression of UGT1A1 (bilirubin levels $>340 \mu\text{mol/L}$) [35]. Type II is less severe in that patients have some UGT1A1 activity albeit at levels that are 10% of normal (bilirubin levels between 150 and 340 $\mu\text{mol/L}$) [35]. Type II is treatable with phenobarbital, which induces UGT1A1 activity. Gilbert's syndrome occurs in roughly 3–13% of the population and is less severe (expression of UGT1A1 is $\sim 30\%$ of normal) than Crigler–Najjar syndrome [32,36]. Typically, Gilbert's syndrome patients require no treatment. Although UGT1A1 polymorphisms have been fairly well characterized clinically, the clinical significance of UGT1A6 and UGT2B7 polymorphisms is still under investigation. Other polymorphisms of UGTs include UGT1A3, UGT1A4, UGT1A7, UGT1A8, UGT1A9, UGT2A1, UGT2B4, UGT2B15, and UGT2B28; however, the clinical relevance of their associated polymorphisms with respect to drug metabolism is unknown at this time [31].

Drug–drug interactions involving glucuronidation seem to be less prevalent than those identified for CYP450s possibly for the following reasons described by Williams *et al.* [37]. UGTs typically have much higher substrate K_m values (300 μM and often much higher) than those of CYP450s (K_m typically around 3 μM) and are usually metabolized by multiple UGTs. Given that the *in vivo* concentrations of most drugs are

usually below $10\text{ }\mu\text{M}$, UGT-metabolized drugs rarely saturate their own metabolism. This along with the fact that K_i values for most UGT inhibitors² are usually $> 10\text{ }\mu\text{M}$ leads to the conclusion that, in general, the AUC_i/AUC ratio will be relatively low even in situations where the fraction of the drug metabolized by a single UGT is high. Consequently, as further pointed out by Williams *et al.* [37], it is not surprising that clinically, UGT drug–drug interactions typically result in differences in *in vivo* exposures that are twofold or less in the presence of coadministered drugs that inhibit UGT. Drug–drug interactions involving glucuronidation, which result in toxicity are rare but have been observed. For example, lamotrigine coadministered with valproic acid increases the incidence of skin rash, which is a known side effect of lamotrigine [39]. A number of intrinsic and extrinsic factors are known to affect drug glucuronidation in humans including age, cigarette smoking, diet, disease state, ethnicity, genetic factors, hormonal factors, and interaction with other drug therapies [9].

Although glucuronidation is typically associated with detoxification, activation via glucuronidation is known to occur. One of the most well-known pharmacologically active glucuronides is morphine-6-glucuronide, which has been reported to be up to 650 times more potent than morphine and is currently in human clinical trials as a parent drug [40]. In addition, potentially toxic glucuronides may be formed. For example, acyl glucuronides that are formed by conjugation of glucuronic acid with carboxylic acids are prone to nucleophilic attack and acyl migration. *In vitro* studies have suggested that toxicity of acyl glucuronides may occur as a result of covalent binding with microsomal proteins. In some cases, acyl glucuronides have been shown to be toxic *in vivo*; however, there are relatively few examples of *in vivo* toxicity [41].

Lastly, glucuronidation is considered a reversible process. Once glucuronide metabolites enter the intestine, they are exposed to enzymes of the intestinal microflora such as β -glucuronidase and become deconjugated back to the parent drug. Often times, the parent drug is then reabsorbed in the lower intestine by a process known as *entero-hepatic recirculation* (Section 6.5). A number of recent review articles are available on UGTs [16,42–47].

6.2.2 Sulfotransferases

Sulfonation is catalyzed by a large family of enzymes known as *sulfotransferases* (SULTs). The SULTs catalyze the transfer of a sulfonate (SO_3^-) group from 3'-phosphoadenosine 5'-phosphosulfate (PAPS) to a $-\text{COH}$, an $-\text{NOH}$ or to an $-\text{NH}$ group. Sulfonation can either be direct, for example, the sulfonation of troglitazone (Fig. 6.2), or occur after oxidation via phase I metabolism, as for example in the sulfonation of hydroxyphenolbarbitol. Sulfonation was first discovered by Baumann [48] in the 1870s when he administered phenol to a patient and recovered phenyl sulfate in their urine. The involvement of PAPS as a cosubstrate was later identified by Robbins and Lipmann [49,50]. The enzyme responsible for the biosynthesis of PAPS in the cytosol is a single bifunctional protein with a molecular weight of $\sim 70\text{ kDa}$ that exhibits both ATP-sulfurylase and APS-kinase-like activity [51]. The capacity of sulfonation is limited by the quantity of PAPS available *in vivo* for conjugation. Sulfonation occurs more rapidly than glucuronidation but is a saturable

²It should, however, be noted that determination of the K_i and K_m values of UGT2B7 and UGT1A9 have often been over estimated because of inhibition of these isoforms by endogenous fatty acids [38].

Figure 6.2 Primary metabolic pathway of troglitazone. *Source:* Adapted from Refs 53–55.

process given the relatively low liver levels ($23 \mu\text{mol/kg}$ liver) of the cosubstrate PAPS compared to glucuronic acid [52]. Hence, when sulfonation metabolic pathways become saturated, glucuronidation typically compensates. For this reason, sulfonation and glucuronidation have been considered as complementary metabolic pathways. As with glucuronidation, sulfate conjugation is a reversible process and sulfate conjugates may be desulfated by sulfatases present in the intestinal microflora. Hence, sulfate conjugates can also undergo enterohepatic recirculation.

The SULTs are widely distributed in most tissues including liver, kidney, lung, skin, breast, gastrointestinal, brain, and platelets [56,57]. However, the highest levels are generally found in the small intestine and liver. Interestingly, the enzyme activity of SULT in the human liver with some substrates such as ethinylestradiol has been shown to vary as much as sevenfold [58]. SULTs are either cytosolic or membrane bound. The membrane-bound SULTs are localized in the golgi apparatus of cells and catalyze the conjugation of endogenous macromolecules such as proteins, peptides, and glycosaminoglycans. The membrane-bound SULTs are not involved in drug metabolism. Conversely, the cytosolic SULTs catalyze the conjugation of lower molecular weight endogenous compounds such as neurotransmitters, bile acids, and steroids in addition to drugs and other xenobiotics. Although the main function of SULT enzymes appears to be in the modulation of physiological processes, they are very important in the metabolism of xenobiotics. Drugs sulfonated by the SULT enzymes include ethinylestradiol, ritodrine, minoxidil, salbutamol, acetaminophen, diflunisal, fenoldopam, terbutaline, troglitazone, and hydroxyphenolbarbitol [56]. Some drugs that are reported to inhibit the SULTs include clomifene, testosterone, danazol, spironolactone, cyproterone, ibuprofen, and tamoxifen [56]. Mefenamic acid and salicylic acid potently inhibit SULT1A1 and SULT1A3 [56]. Additional SULT substrates and

Source: Adapted from Ref. 56.

inhibitors are listed in Table 6.2. In humans, 13 SULT isoforms have been identified to date and belong to one of the four SULT families: SULT1, SULT2, SULT4, or SULT6 [57]. SULT1 and SULT2 families have been identified as the most important in xenobiotic drug metabolism. The cloned human SULTs contain 284–365 amino acids, have subunit molecular weights ranging from 30 to 35 kDa, and are typically present as dimers in solution [59–61]. The three-dimensional structures for most of the human SULTs have been elucidated and include SULT1A1, 1A3, 1B1, 1C1, 1C2, 1C3, 1E1, 2A1, 2A3, 2B1a, 2B1b, and 4A1³ [62,63]. Data from the crystal structures have revealed a highly conserved PAPS binding pocket with a highly variable substrate binding pocket, which is consistent with their observed overlapping substrate specificity. The recently discovered SULT4A1 is an unusual SULT because of its atypical structure, function, and unique binding properties. In fact, it is inactive and does not catalyze sulfonation reactions. Interestingly, it has been shown to bind well to neurotransmitters, such as epinephrine and norepinephrine, suggesting that it may be involved in brain function [63].

Polymorphisms have been identified in several human SULT genes, including those encoding SULT1A1, SULT1A2, SULT2A1, SULT1C2, and SULT1E1. However, SULT1A1 and 1A2 are the only SULT isoforms for which common genetic polymorphisms are known and have been investigated in epidemiological studies [56]. Polymorphisms of SULT 1A1 have been attributed to carcinogenicity via activation of endogenous substrates. Patients homozygous for SULT1A1*2 have 10-fold lower phenol SULT activity than those homozygous for SULT1A1*1 and have been found to have an increased risk for lung, breast, and other cancers [64–66]. Thus far, despite being polymorphic, few or no clinically relevant drug–drug interactions involving SULTs have been reported [67].

Unstable sulfate conjugates have been shown to be genotoxic. Examples of genotoxic compounds that form unstable sulfate conjugates through binding to DNA are safrole and tamoxifen [68,69]. Additionally, sulfoconjugates are anionic species and

³The human SULT crystal structures and original references are summarized in these two sources.

do not freely permeate cell membranes. This, consequently, may lead to specific sites of SULT-dependent genotoxins. Given sulfate is a good leaving group, cleavage of the C–O bond in sulfoconjugates results in the formation of a carbocation, which is a strong electrophilic species. These reactive species are often hepatotoxic. Examples of hepatotoxic sulfates include phenacetin that binds to microsomal proteins and troglitazone, which is a potent bile salt export pump (BSEP) inhibitor [70]. Inhibition of BSEP causes cholestasis, a condition that results from lower bile salt secretion and reduced bile flow.

6.2.3 Glutathione-S-Transferases

GSH is a tripeptide comprised of the amino acids glycine, cysteine, and glutamic acid and is the cosubstrate for GST. GSH has a very high reduction potential with an E_h of -0.24 V in pH 7.0 phosphate buffer at 40°C (E_h in human liver is -0.26 V) and is very effective in reducing highly reactive electrophilic species [71,72]. Cells often employ GSH to inactivate reactive (toxic) species that are either present as a result of normal cellular metabolism (e.g., H_2O_2 or $\text{O}_2^{\cdot-}$) or are introduced as a xenobiotic. The balance of reduced GSH and oxidized GSH (GSSG) is critical to preventing damaging levels of oxidative species from accumulating within cells. GSH has been shown to be essential in apoptosis and embryonic development [73]. Another indication of its importance is the high intracellular levels of GSH, which can reach 8–10 mM in some tissues [74].

In many cases, oxidative species can be scavenged directly by GSH, however, certain chemical species require enzymatic catalysis for conjugation. Glutathione-S-transferases catalyze the conjugation of GSH with an electrophilic substrate molecule such as an epoxide or quinone. Drugs that are substrates for GSTs include acetaminophen and valproic acid as well as the anticancer drugs cyclophosphamide, busulfan, and melphalan [75–77]. Figure 6.3 shows the GSH conjugation of melphalan [78]. In drug metabolism, GSTs are typically associated with the conjugation of xenobiotics with GSH; however, they are also known to catalyze reduction, thiolysis,

Figure 6.3 Metabolic pathway of melphalan. *Source:* Adapted from Refs 78–80.

and isomerization reactions [77]. Conjugation with GSH usually leads to less reactive products that are readily excreted. The end products of GST conjugation are either excreted by transport proteins into the bile or converted to *N*-acetyl cysteine conjugates and excreted into the urine. In some instances, GSH conjugates can be more reactive than their respective parent compounds. For example, conjugation of GSH with 1,2-dihaloethane results in genotoxic products [77]. Like most other conjugative enzymes, GSTs have endogenous substrates such as prostaglandins.

Most GSTs are cytosolic enzymes, but there are examples of membrane-bound GSTs such as MGST1, MGST2, and MGST3 which are located in the endoplasmic reticulum. A mitochondrial human GST, GSTK1-1 has also been identified. Cytosolic GSTs have a monomeric molecular weight typically around 25 kDa, but generally occur as homo- or heterodimers [81–83]. The cytosolic GSTs have been found in most cells and the crystal structures for many have been resolved. Like UGTs and SULTs, there are different isoforms of GSTs, but the naming convention is slightly different. On the basis of amino acid similarities, there are seven classes of cytosolic GSTs: alpha, mu, pi, sigma, theta, omega, and zeta [77,84]. Polymorphisms are also found within each class of GSTs; however, the focus of this chapter is centered on those that are clinically relevant. The greatest impact of GST polymorphism on drug metabolism arises in the mu and theta classes with the GSTM1*0 and GSTT1*0 genotypes, which are referred to as *null alleles* in which the gene encoding GSTM1 or GSTT1 is absent. These individuals have no active enzyme and are associated with an increased risk for certain cancers [85]. Polymorphisms in the *GSTA1* gene have been shown to cause increased variability of busulfan conjugation, while GSTP1*1, GSTP1*2, and GSTP1*3 polymorphisms have been associated with higher rates of certain cancers [77]. GSTs are induced by increases in the levels of oxidative species that are often produced by electrophiles. The process of induction involves a transcription factor known as *nuclear factor* (erythroid-derived 2)-like 2 (Nrf2), which is released in the presence of electrophiles and binds to the antioxidant response element promoter regions of the genes encoding some of the GSTs (e.g., GSTA1 and GSTA3).

6.2.4 Methyltransferases

MTs catalyze the transfer of a methyl group from a cosubstrate known as *S*-adenosylmethionine (SAM) to an oxygen, sulfur, or nitrogen functional group on the substrate. There are over 100 methyltransferases, however, only a few have been found to catalyze the metabolism of drugs, including catechol methyltransferase (COMT), thiol methyltransferase (TMT), thiopurine methyltransferase (TPMT), and nicotinamide *N*-methyltransferase (NNMT). Nicotinic acid (also known more commonly as *vitamin B₃* or *niacin*) is converted to nicotinamide *in vivo* and subsequently methylated by NNMT [86]. Nicotinic acid at therapeutic doses of 2000 mg has been used to treat atherosclerosis [87]. Histamine *N*-methyltransferase (HNMT) does not catalyze the conjugation of any drugs; however, a number of drugs including promethazine and the antimalarials pyrimethamine and chloroquine have been identified as inhibitors of this enzyme [88].

COMT was first identified as responsible for the methylation of epinephrine and partially characterized by Axelrod [89] in the late 1950s. COMT catalyzes the *O*-methylation of catechols and catecholamines such as dopamine. A single gene containing six exons codes for both cytosolic (*S*-COMT) and membrane-bound COMT

(MB-COMT) [90]. The molecular weights are 24.4 and 30.0 kDa, respectively [91]. Unlike most other small molecule methyltransferases, COMT requires Mg^{2+} for its catalytic activity [90]. The active site of the enzyme contains two binding domains, one for SAM and other for the substrate. The transfer of a methyl group from SAM to the catechol occurs via an S_N2 -like transition state where the hydroxyl group of the catechol attacks the nucleophilic methyl group of SAM. COMT is found in most tissues including brain, lung, and red blood cells but the highest levels are expressed in the liver and kidney. The endogenous substrates of COMT include L-dopa, dopamine, norepinephrine, and epinephrine [92]. Drugs metabolized by COMT include rimeterol, dobutamine, dihydroxyphenylserine, isoprenaline, and carbidopa. Inhibitors of COMT include nitrocatechols such as entacapone, nitecapone, tolcapone, and vinylphenolketones [90]. COMT is polymorphic in humans. One polymorph known as val¹⁵⁸met, has been shown to cause reduced enzyme activity (three- to fourfold) and was originally thought to be linked to an increased risk of breast cancer. However, recent studies have failed to show a correlation of this polymorph to breast cancer [93–96]. Methylation differs from sulfonation, glucuronidation, and GSH conjugation as methyl conjugates are less polar than the parent drug and therefore may not be more easily eliminated [97].

Thiopurine drugs such as azathiopurine, 6-mercaptopurine (6-MP), and 6-thioguanine are S-methylated by TPMT (Fig. 6.4). These drugs are used to treat a wide variety of conditions including leukemia, Crohn's disease, and ulcerative colitis. TPMT was first characterized by Woodson and Weinshilboum in 1983 [98]. It is a cytosolic enzyme of ~36 kDa in molecular weight [98]. TPMT is polymorphic with 18 mutant alleles that contribute to the narrow therapeutic index of thiopurine drugs because of their poor metabolism in the body [99]. Of these alleles, TPMT*2, TPMT*3A, and TPMT*3C have been shown to be associated with most of the intermediate (~11% occurrence) or poor (~0.3% occurrence) enzyme activity in humans [100,101]. Noncompetitive inhibitors of TPMT include naproxen,

Figure 6.4 Metabolic pathway of 6-mercaptopurine (6-MP). *Source:* Adapted from Refs 103–105.

mefenamic acid, and tolfenamic acid and suggests the potential for clinical drug–drug interactions between NSAIDs and thiopurines [99]. Other inhibitors of TPMT include the diuretics—furosemide, bendroflumethiazide, and trichlormethiazide; and the 5-aminosalicylates—mesalazine, olsalazine, and sulfasalazine [99]. Another S-methyl transferase found in human red blood cell membranes known as TMT also plays a role in drug metabolism and catalyzes the S-methylation of the angiotensin-converting enzyme (ACE) inhibitor captopril as well as other thiol compounds such as N-acetylcysteine and 7 α -thio-spirolactone [102].

6.2.5 N-Acetyltransferases

NATs (also referred to as *arylamine N-acetyltransferases*) catalyze the transfer of an acetyl group from acetyl CoA to aryl amines and N-hydroxyaryl amines. An N-acetylation metabolite of *p*-aminobenzoic acid in humans was first described in 1926 [106]. Similar to methylation, N-acetylation differs from other conjugation reactions, in that it also produces metabolites that are less polar and less water soluble than their parent drug forms. There are two human forms of NAT, NAT1 and NAT2, both of which are comprised of 290 amino acids and are ~33.5 kDa in molecular weight. NAT1 and NAT2 are expressed from separate genes on chromosome 8 with ~81% homology of their amino acid sequences [107]. The crystal structures of human NAT1 and NAT2 were solved in 2007 by Wu *et al.* [108], providing additional insight into the substrate specificity of these two enzymes. The active site of both NATs is highly conserved and exerts its catalytic activity via cysteine, histidine, aspartic acid and amino acid residues. The kinetics of these enzymes proceed via a ping-pong bi-bi reaction mechanism. Therapeutic agents that are NAT substrates include isoniazid, hydralazine, phenelzine, sulphamethazine, endralazine, *p*-aminosalicylic acid, procainamide, nitrazepam, debrisoquine, and dapsone [109,110]. Interestingly, NAT1 has only one proposed endogenous substrate (*p*-aminobenzoyl glutamic acid), while no endogenous substrates have been identified for NAT2 [111–113]. Drugs such as ketoprofen, ibuprofen, paclitaxel, and salicylamide are inhibitors of NATs [114]. Despite the similarities between the two isoforms, they are quite different in their substrate specificity and tissue distribution. NAT1 is widely expressed in many tissues, while NAT2 is found primarily in the liver and gut.

Both forms are polymorphic, however, the polymorphism of NAT2 has been more extensively studied and has been implicated in the variability of the therapeutic activity and toxicity of isoniazid and other hydrazine drugs. According to the most recent update (March 12, 2010) published online by the University of Louisville, 26 NAT1 alleles and 62 NAT2 alleles have been identified (<http://louisville.edu/medschool/pharmacology/consensus-human-arylamine-n-acetyltransferase-gene-nomenclature/>). The involvement of NAT2 in the metabolism of isoniazid is presented in Fig. 6.5 [115]. It is estimated that in humans 50–90% of isoniazid is metabolized to acetyl isoniazid [116,117]. NAT2*5B, NAT2*6A, and NAT2*7B have been shown to be the mutant alleles primarily responsible for intermediate/poor metabolism of isoniazid in humans [118–120]. The rate of occurrence of poor/intermediate metabolizers in various ethnic populations has been found to be highly variable, but has been reported to be ~10–30% in Asians and 50–60% in Caucasians [121–123]. Poor metabolizers treated with isoniazid are at a higher risk to develop hepatic disorders and peripheral neuropathy [124–126]. NAT2 polymorphisms have also been attributed

Figure 6.5 Metabolic pathway of isoniazid. *Source:* Adapted from Refs 115 and 134.

to drug–drug interactions when rifampin and doxycycline are used in combination. In rapid acetylators, rifampin levels are higher and doxycycline levels are lower compared to slow acetylators [127]. Additionally, NAT polymorphisms have been associated with an increased risk for cancer. For example, NAT1 polymorphisms have been linked to myeloma, lung, bladder, and other cancers; NAT2 polymorphisms have been linked to liver, colorectal, non-Hodgkin lymphoma, bladder cancer, and other cancers [128]. Although acetylation is generally a detoxification process, it sometimes results in bioactivation. For example, in addition to *N*-acetylation, both NAT1 and NAT2 can catalyze *O*-acetylation. Hence, some aromatic amines are oxidized to form hydroxylamines. Through heterolytic cleavage of the hydroxylamine, an unstable aryl nitrenium can be produced that ultimately can form adducts with DNA and proteins [129]. Similar to other phase II conjugating enzymes, there are a number of acetyltransferases (such as histone acetyl transferase) that are only involved in the acetylation of endogenous substrates. Research on NATs remains very active and a number of reviews have been written that summarize these studies [107,114,123,128, 130–133].

6.2.6 Amino Acid Conjugation

Amino acid conjugation, the first conjugation reaction to be identified in humans, was observed with substrates that have a carboxylic acid functional group. In humans, glycine is typically the conjugating amino acid, but in other species, additional amino acid conjugates such as glutamine, taurine, ornithine, aspartamine, alanine, and histidine have been observed. The enzymes that catalyze amino acid conjugation (acyl CoA ligase and *N*-acyltransferase) are located in the mitochondria of the liver. Hence, amino acid conjugation involves a coupled enzyme system and occurs in a number of steps [135]. First, the xenobiotic carboxylic acid group is activated by ATP. This is followed by the formation of a xenobiotic-CoA-thioester intermediate formed via the acyl CoA ligase (synthetase) catalyzed reaction of the ATP-activated carboxylic

Figure 6.6 Glycine conjugation of benzoic acid. *Source:* Adapted from Ref. 138.

acid with coenzyme A. In the last step, the activated acyl group is conjugated via *N*-acyltransferase with the respective amino acid, and coenzyme A is regenerated. Amino acid conjugation was first reported in humans by Ure in 1841 and confirmed by Keller in 1842 when they independently identified hippuric acid as a metabolite formed from conjugation of benzoic acid with glycine [136,137]. Aspirin is extensively (~75%) conjugated with glycine, and benzoic acid (a food preservative that has been used to treat hyperammonemia) is exclusively conjugated with glycine [135,138]. The glycine conjugation of benzoic acid is depicted in Fig. 6.6. Given that they are generally low molecular weighted and polar, amino acid conjugates are readily eliminated in urine. As a whole, amino acid conjugation is considered a detoxification pathway. However, it is interesting to note that a reactive acyl thioester intermediate is formed in the process that is not always subsequently conjugated. For example, the anticonvulsant drug valproic acid forms the reactive acyl thioester intermediate but not the amino acid conjugate. Though the mechanism of toxicity is not fully defined for valproic acid, it is thought that the valproic acyl thioester is responsible at least in part for the hepatotoxicity observed in some individuals receiving this drug; most likely due to interference with mitochondrial β -oxidation [135,139]. Glycine conjugation (like sulfonation) is readily saturated at high substrate circulating concentrations and is compensated for by glucuronidation. Amino acid conjugation is not a major pathway in the metabolism of most drugs or xenobiotics. Consequently, amino acid conjugation as a route of xenobiotic/drug metabolism is not as well characterized [135].

6.3 EXCRETION OF DRUGS IN HUMANS AND ROLE OF TRANSPORT PROTEINS

6.3.1 Bile versus Urine as a Route of Excretion

The exact mechanism by which compounds are directed for elimination into the urine versus the bile is still not known. It was originally proposed that the main determining factors were molecular weight, polarity, and metabolism [140]. In humans, the molecular weight cutoff for biliary excretion is in the 500–600 Da range. Notable differences in this threshold are observed between species. For example, in rats, guinea pigs, and rabbits, the molecular weight cutoffs are around 325, 400, and 475 Da, respectively [141]. In general, drugs excreted into bile are strongly polar, hence most xenobiotics

and drugs excreted into the bile are in their conjugated form. However, conjugation is not always a prerequisite for biliary excretion. Though the above factors are involved, it is now becoming clear that uptake and excretion in the liver and kidney is largely determined by transport proteins. These proteins dictate to a large degree the elimination pathway of most drugs, xenobiotics, and their respective metabolites. Recent research conducted in rats that are genetically deficient in multidrug resistance-associated protein (Mrp2) has suggested that increased biliary excretion of β -lactam antibiotics by Mrp2 correlates with higher molecular weight [142].

6.3.2 Renal and Hepatic Transport Proteins

Transport proteins are involved in drug absorption, distribution, metabolism, and excretion and are most highly expressed in the intestine, liver, and kidney. The discussion here is primarily focused on transport proteins involved with the excretion of drug conjugates. Membrane transporters belong to one of two superfamilies: the ABC or the SLC. In the human ABC family, there are 49 transporters, which are divided into 7 subfamilies (A to G) [143]. The molecular weight of transporters in the ABC family ranges from 150 to 200 kDa. Each ABC transporter has two transmembrane domains and two ATP-binding domains [144]. The binding and hydrolysis of ATP is required to mediate transport. The SLC family on the other hand, is quite large consisting of ~ 48 subfamilies (SLC1-SLC46, SV2, etc.) with a total of over 380 transport proteins [145]. The SLC proteins consist of 12 putative transmembrane domains and range in molecular weight from 50 to 100 kDa [146].

Some of the transporters involved in biliary and renal uptake and excretion include the BSEP (BSEP, ABC), breast cancer resistance protein (BCRP, ABC), organic cation transporters (OCTs, SLC), organic cation/ergothioneine transporter (OCTN, SLC), OATs (OATs, SLC), organic anion transporting polypeptide (OATP, SLC), multidrug and toxin extrusion protein (MATE, SLC), multidrug resistance proteins (MRPs, ABC), sodium taurocholate cotransporting polypeptide (NTCP, SLC), peptide transporter (PEPT, SLC), P-glycoprotein (P-gp, MDR1, ABC), and urate transporter (URAT, SLC) [147]. Several of the SLC transporters such as a number of the OATs are bidirectional and transport substrates in both directions.

6.3.3 Biliary Excretion

The human liver weighs ~ 1400 – 1600 g and is a highly perfused organ receiving 25–30% of cardiac output [148]. The key component of liver function is the hepatocyte, which performs many tasks including the production of bile. Bile produced in hepatocytes is collected in the bile canaliculi where it flows into the bile ducts. The bile ducts either direct bile into the duodenum to aid in digestion or direct flow into the gall bladder for storage. Once in the intestine, 95% of the bile salts are reabsorbed in the terminal ileum and returned to the liver via the portal vein where they are reused by the hepatocyte. The liver is capable of producing ~ 1 L of bile per day and human bile flow typically ranges from 1.5 to 2.0 mL/min/kg [149].

Once a drug or metabolite is taken up into the hepatocyte via portal vein circulation, there are two paths it can follow. It can either be secreted back into systemic circulation or excreted as unchanged drug and/or as metabolite into the bile. Drug uptake, normally occurs at the sinusoidal membrane while excretion generally occurs

at both the sinusoidal and canicular membranes. Drugs and metabolites excreted into the sinusoidal blood via the basolateral sinusoidal membrane typically end up being eliminated in the urine while those excreted in bile via the canicular membrane end up in the intestine where they are eliminated in the feces or can potentially undergo reabsorption via a process known as *enterohepatic recirculation* (Section 6.5).

6.3.4 Transporters Involved in Hepatic Drug and Metabolite Uptake and Excretion of Phase II Metabolites

In order to be excreted via the hepatobiliary route, parent drug and/or its respective metabolites which are in the systemic circulation and not already in the hepatocyte (e.g., extrahepatic metabolites) must first be taken up into the hepatocyte. Transporter proteins in the OAT, OATP, and OCT families are involved in the ATP-mediated uptake of drugs and metabolites into the hepatocyte. The OATs transport anions that are <500 Da in MW and the OCTs transport hydrophilic low molecular weight (<400 Da MW) monovalent cations [146].

Transporters involved in the biliary excretion of drugs and metabolites out of the hepatocyte into the bile or sinusoidal blood include BCRP, BSEP, P-gp, several of the MRPs and MATE1. While the role of BSEP in the transport of drugs and conjugated metabolites remains unclear, several drugs have been shown to inhibit BSEP (cyclosporine A, bosentan, fluvastatin, glibenclamide, troglitazone, and rifampicin), potentially leading to cholestasis [70]. Most conjugated metabolites are very hydrophilic and cannot passively diffuse out of hepatocytes and must therefore be actively transported. Though still under investigation, the main transport proteins involved in the biliary and basolateral excretion of glucuronide, sulfate, and GSH metabolites are MRP2, BCRP, MRP3, and MRP4 [20,147]. Most glucuronide conjugates that are excreted into the bile are MRP2 substrates, whereas most sulfate conjugates are BCRP substrates [20,147].

There are a number of ATP-mediated transporters responsible for basolateral excretion into the sinusoidal blood. From the MRP family, these include MRP3, MRP4, MRP5, and MRP6 [20]. Of these, MRP3 is efficient in transporting both glucuronide and sulfate conjugates, but its role in transporting GSH conjugates remains unclear [20,147]. The most notable conjugated-drug substrates of this transport protein are morphine-3-glucuronide and morphine-6-glucuronide. MRP4 has been shown to transport both sulfate and glucuronide conjugates in addition to GSH conjugates but appears to have a higher affinity for sulfate conjugates [20,147]. GSH conjugates are also transported by MRP5 and MRP6 [20,147]. However, little is known of MRP5 and MRP6 in their ability to transport conjugated organic anions [20,147].

Biliary transport of sulfate, glucuronide, and GSH metabolites is primarily mediated by MRP2 [150]. The most notable substrates include both the parent drugs and conjugates of ceftriazone, ampicillin, and dibromosulfophthalein. MRP2 is inactive in Dubin–Johnson syndrome leading to impaired secretion of bilirubin in the hepatocytes [151]. Hence, by examining drugs known to be transported by MRP2 in these patients, one can confirm the physiologic role of MRP2. The recently identified canicular drug transport protein BCRP also excretes many sulfate and glucuronide conjugates into bile. Although other canicular transporters, BSEP, MDR2, and P-gp transport a number of drugs, they do not appear to be involved in the biliary transport of sulfate, glucuronide, or GSH conjugates [20].

6.3.5 Renal Excretion

The kidneys receive about 20% of the cardiac output. The nephron in the kidney is where the process of glomerular filtration, tubular secretion, and tubular reabsorption occurs and defines the rate of renal clearance of drugs ($CL_r = R_r/C_p$, where CL_r is the renal clearance, R_r is the renal excretion rate, and C_p is the plasma concentration). When no other factors are involved such as protein binding or secretion/reabsorption, renal clearance of the drug will be equivalent to the glomerular filtration rate (GFR). The glomerulus filters arterial blood and only molecules <5 kDa in molecular weight can pass through the membranes of the glomeruli [152]. Consequently, protein-bound drugs do not pass through the glomeruli. In adults, the GFR is ~120–130 mL/min. The process of reabsorption occurs along the proximal, distal, and collecting tubules with most of the reabsorbed components (e.g., glucose and lipid soluble components) ending up back in the plasma. The net result is that only 1–2 mL/min of the total volume filtered by the glomeruli ends up being eliminated in the urine. The pH of the tubular fluid ranges from 4.5 to 8 and is important in determining if drugs are excreted into the urine or reabsorbed. While uncharged nonionic molecules can diffuse passively through the cell membrane, the renal secretion of drugs (which are usually ionic) occurs against a concentration gradient and therefore requires active transport. As mentioned above, if a drug is not protein bound, secreted, or reabsorbed (e.g., digoxin and kanamycin), then its renal clearance will be equivalent to the GFR. Although some drugs are reabsorbed by the proximal tubules via active transport such as β -lactam antibiotics (e.g., dicloxacillin), reabsorption of most lipid soluble organic ions occurs passively [153,154]. A second mechanism of reabsorption in the kidney is endocytosis. Endocytosis in the kidney occurs by the formation of vesicles along the brush border membrane, which can take up fluids and compounds [154]. Although drugs are primarily metabolized in the liver, the kidney is also capable of oxidative, reductive, and conjugative (glucuronide, sulfate, and GSH) metabolism of drugs [155].

In summary, renal excretion of drugs occurs via a combination of three processes: (i) glomerular filtration, (ii) renal tubule secretion (the basolateral uptake and apical efflux transporters are involved in this process), and (iii) renal tubular reabsorption (apical transporters are involved in this process). Transporter proteins mediate uptake and excretion as well as secretion processes. For example, MDR1/P-gp is localized at the apical brush border membrane of the proximal renal tubule and is involved in secretion processes in the kidney.

6.3.6 Transporters Involved in Renal Uptake and Excretion

In the kidney, efflux transporters are located on the luminal (apical) brush border membrane and can transport an unchanged drug or its metabolites into urine. The primary site of transport of drugs and metabolites from blood into urine is the proximal tubule [154]. The uptake of drugs from systemic circulation by the basolateral membrane of proximal renal epithelial cells is mediated by several transporter families including OCT, OAT, and OATP [156,157]. There are also bidirectional transporters that, in addition to excretion into the urine, can transport endogenous substrates and potentially drugs from the urine back into the renal epithelial cells. These include OAT4, URAT1, and PEPT1/2. For example, PEPT2 is involved in the reabsorption of peptidic drugs, while the bidirectional transporters URAT1 and OAT4 thus far have only been shown

to be involved in the reabsorption of endogenous substrates such as urate [146,158]. Transporters involved in the renal excretion of drugs and metabolites out of the kidney proximal tubule epithelia into the urine include OAT4, MRP2, MRP4, MDR1/P-gp, MATE1, and OCTN1 [146,147]. As in hepatobiliary excretion, MRP2 is primarily involved in the renal excretion of glucuronide, sulfate, and GSH conjugates. GSH S-conjugates of polyhaloalkanes and hydroquinones have shown nephrotoxic potential as a consequence of active secretory transport and ultimate accumulation of conjugates in high concentration in the proximal renal tubules [159].

6.3.7 Drug Interactions and Clinical Relevance

Given the impact of transporters on the pharmacokinetics (PK) of drugs and the potential for drug–drug interactions, an international transporter consortium was formed and discussed the issues surrounding drug transporters relating to drug–drug interactions. A recent review article summarizes their findings and provides suggested decision trees for handling potential transporter interactions [147]. As pointed out in this review by Giacomini *et al.*, a number of transporters including OATP, OAT, OCT, P-gp, and BCRP have been implicated in drug–drug interactions. Some of the drug pairs and corresponding transporters involved in these interactions are pravastatin/cyclosporine (OATP), bosentan/rifampicin (OATP), acyclovir/probenecid (OAT), pilsicainide/cimetidine (OAT), digoxin/ritonavir (P-gp), and topotecan/GF120918 (BCRP) [147].

Not all drug–drug interactions involving transporters are adverse and some have been exploited to extend the desired therapeutic effect. For example, an inhibitor of OAT-mediated tubular secretion, probenecid, has been used clinically to extend the pharmacological activity of cephalosporins and penicillins in patients [160,161]. Probenecid coadministered with cephadrine resulted in a 2.4-fold increase in AUC [162]. Similarly, coadministration with dicloxacillin resulted in a 1.9-fold increase in AUC [163]. In both cases, renal clearance was reduced by inhibiting tubular secretion (1.8-fold for cephadrine and 3.6-fold for dichloxacillin). In fact, this property of probenecid was used during World War II to increase the length of efficacy of penicillin, which was in short supply [154].

6.4 ELIMINATION PATHWAYS IN HUMANS

6.4.1 Feces, Urine, and Other Routes of Drug Elimination in Humans

The most common routes of drug and metabolite elimination in humans are via the urine and feces. As discussed above, drugs and metabolites, which are substrates for the efflux transporters in the proximal tubule end up being excreted out of the kidney into the urine. Drugs and metabolites, which are substrates for efflux transporters in the liver, end up being excreted via the bile into the intestine where they are eliminated in feces.

Excretion of drugs into other body fluids (saliva, sweat, tears, and breast milk) and tissues (hair and skin) generally represent minor elimination pathways in humans. Volatile drugs such as the anesthetic halothane may be primarily eliminated unchanged in expired air, whereas other nonvolatile drugs, for example, aminopyrine may generate CO₂ as a metabolite, which is eliminated via the breath [164,165].

6.4.2 Mass Balance Studies in Humans

The most comprehensive way to quantify drug and metabolite elimination in feces and urine is through a human mass balance study. In mass balance studies, radiolabeled (usually ^{14}C) drug is dosed via the therapeutic administration route. The position of the radiolabel in the compound is chosen such that it is metabolically stable to potential biotransformation pathways. Samples of blood, plasma, urine, and feces are collected, and the amount of radioactivity in the samples is quantitated using a variety of analytical techniques. Human mass balance studies are required by the FDA for a New Drug Application (NDA) approval. Complete mass balance (100% recovery of radioactive material) is rarely achieved because of sampling or analytical issues. However, recoveries of greater than 80% are normally achievable in human mass balance studies, and no less than 90% recovery has been recommended in animal studies as a minimum cut-off for acceptability [166]. Recovery in human mass balance studies is generally lower than that obtained from rat or dog studies, most likely due to the difficulty in collecting every last drop of excreta samples from human subjects. For compounds and metabolites with a very long half-life, it is more difficult to achieve mass balance, and sample collection times and study objectives should be adjusted accordingly. Low recovery (e.g., lower than 80% in human studies) does not necessarily invalidate the study if the objectives of the mass balance study have been largely met. However, significantly lower recovery could indicate covalent binding or noncovalent tissue sequestration and raise safety concerns regarding the drug. In addition to providing information on the quantities of unchanged drug and its metabolites that are eliminated via the excreta, mass balance studies can also provide important data regarding the following [167,168]:

1. Clearance mechanism of the drug
2. Levels of circulating metabolites versus levels of circulating parent drug
3. Ratio of blood/plasma levels of the drug and metabolites
4. Appropriateness of the species used in the preclinical safety studies (e.g., no unique human metabolites are observed)
5. Pharmacologically active or toxic metabolites
6. Proportion of unchanged drug eliminated.

Comparison of metabolite profiles from human mass balance studies to those obtained from preclinical safety studies can divulge differing levels of active/toxic metabolites or the presence of unique human metabolites that may help explain why human toxicity differs from that observed in the animal species used for preclinical safety studies. Given that some drugs are extensively metabolized and the resulting metabolites were not routinely identified or quantified, guidelines were developed in order to reduce clinical toxicity/safety issues arising from the above scenario. The guidelines were first presented entitled as “Metabolites in Safety Testing,” which is often referred to as the *MIST document*⁴ [170,171]. They ultimately served as a basis for the FDA guidance document entitled “Safety Testing of Drug Metabolites,” which was implemented in February, 2008.

A number of excellent reviews have recently been published on this topic [166,168,169].

6.5 ENTEROHEPATIC RECIRCULATION

Enterohepatic recirculation is the process by which a drug or its conjugated metabolites (e.g., indomethacin glucuronide) undergoes biliary excretion followed by reabsorption in the intestine [172]. It is usually observed in the drug concentration–time PK profiles as one or more peaks that occur after the initial $C_{\max}$ and generally increases the half-life and systemic exposure (AUC) of the drug. In some cases (e.g., the drug ezetimibe), the appearance of these peaks in the concentration–time profiles coincide with gall bladder emptying via the Sphincter of Oddi into the small intestine [173]. Enterohepatic recirculation can occur with either the parent drug or a conjugated metabolite. Conjugated metabolites, such as sulfates or glucuronides, are generally converted back to parent drug by the β -glucuronidases or sulfatases present in the microflora of the intestine. Enterohepatic recirculation also occurs for some endogenous compounds such as bilirubin and bile acids. In addition, GSH conjugates excreted into the bile have also been known to undergo enterohepatic recirculation [174]. Given that biliary excretion of conjugates is mediated by transport proteins such as MRP2, drug and metabolite transport is an important component of enterohepatic recirculation. Clinically, enterohepatic recirculation is impacted by various inhibitors and inducers of drug transport and disease states that affect transporter activity. Hence, overall characterization of this recycling process requires determination of the rate of biliary excretion and re-excretion, absorption in the intestine, and elimination of the parent compound and metabolites in the feces and urine [175]. Recycling ends when the endogenous or exogenous compound is ultimately eliminated in the feces or urine. Many drugs undergo enterohepatic recirculation, including digoxin, morphine, indomethacin, and erythromycin. Other drugs that undergo enterohepatic recirculation are summarized in Table 6.3 [174]. The extent of enterohepatic recirculation can be impacted by factors that mediate the absorption, biotransformation, and excretion of the drug and its metabolites. In humans, these factors include genetics, age, gender, diet, disease states, and coadministration of other drugs or xenobiotics [174].

6.6 IMPACT OF HEPATIC AND RENAL IMPAIRMENT ON DRUG ELIMINATION

When liver function is impaired, the hepatic clearance of most drugs cleared via this pathway will be compromised leading to drug accumulation and toxicity. Ultimately, a dose reduction is typically required. The phase I CYP450 enzymes are generally impacted to a greater degree by liver impairment than the phase II conjugation enzymes. For example, hepatic impairment has been shown to impact the CYP450 enzymes

TABLE 6.3 Examples of Drugs Excreted in Human Bile

Ampicillin	Erythromycin	Irinotecan	Sulfamethoxazole
Cephazolin	Estradiol Ezetimibe	Lorazepam	Testosterone
Diazepam Digoxin	Gentamycin	Methotrexate	Tetracycline
Doxycycline	Indomethacin	Morphine	Troglitazone
		Phenytoin	Valproic acid

involved in the clearance of antiarrhythmic drugs but not phase II metabolism [176]. In another study, the extent of formation of dabigatran glucuronides, as well as glucuronidation capacity, was found to be unchanged in moderate liver disease [177].

Renal impairment has led to implementation of modified dosing regimens for elderly patients with impaired kidney function and has resulted in FDA guidelines for when and how to conduct renal impairment studies [178,179]. Interestingly, data suggests that kidney disease can impact transporters and metabolic enzymes in the liver and gastrointestinal tract, potentially because of the accumulation of uremic toxins. Currently, it is postulated that uremic toxins such as urea, parathyroid hormone, indoxyl sulfate, and cytokines might cause transcriptional/translational modifications or inhibition of DMEs and transporters and data collected thus far seem to support this theory [180]. Assessment of the impact of renal impairment on the systemic exposure of new molecular entities from recently submitted investigational new drug applications (INDs) provided evidence that renal impairment can affect the PKs of drugs that are predominately eliminated by nonrenal processes such as metabolism (CYP and non-CYP) and/or active transport [181].

6.7 NUCLEAR RECEPTORS IN HUMAN DRUG CONJUGATION AND TRANSPORT

6.7.1 Nuclear Receptors

NRs are proteins that control the transcriptional genes that modulate the levels of numerous proteins including the phase II conjugating enzymes and phase III transport proteins. Induction of a particular protein occurs when the transcriptional gene is activated via the NR. Transcriptional activation results in the expression of higher levels of the corresponding protein in tissues. When agonist binding results in conformational changes in the ligand binding domain of NRs, they are translocated to the nucleus, and subsequent involvement of additional transcription factors (such as RNA polymerase) allow transcription of mRNA and ultimately expression of the protein/enzyme [182]. Similar to the phase I, II, and III DME systems, NRs are widely expressed in many tissues, but the highest levels are found in liver and intestine. The NRs comprise a superfamily of receptors and include the aromatic hydrocarbon receptor (AhR), CAR, farnesoid X receptor (FXR), glucocorticoid receptor (GR), hepatocyte nuclear factor (HNF), nuclear factor erythroid 2-related factor 2 (Nrf2), peroxisome proliferator-activated receptor (PPAR), PXR, and the vitamin D receptor (VDR).

6.7.2 Transcriptional Regulation of Drug Conjugation and Transport in Humans

The phase II drug-conjugating enzymes are regulated by PXR, CAR, FXR, and VDR with some involvement of AhR, PPAR, HNF, and Nrf2 [183,184]. PXR and CAR are the primary regulators of the phase II enzymes. Through experiments conducted in human cell lines such as human hepatoma Hep G2 cells, UGT1A1 and UGT1A3 expression was shown to be increased by activation of PXR with rifampicin [185]. Similar experiments on CAR utilizing human hepatocytes demonstrated that the expression of GSTA2, UGT1A1, and SULT1A1 was increased by activation

with 6-(4-chlorophenyl)imidazo[2,1-*b*][1,3]thiazole-5-carbaldehyde *O*-(3,4-dichlorobenzyl)oxime (CITGO) [186]. Overall, UGTs are regulated by the NRs—AhR, CAR, PPAR, and PXR [42]. The NRs involved in the regulation of all human SULTs have not yet been fully delineated, but thus far AhR, CAR, FXR, GR, PPAR α , and PXR have been shown to be potentially involved in the induction of the SULT enzymes [61,187]. SULTs do not appear to be impacted by induction to the same degree as the UGTs [188,189]. In fact, those that appear to be inducible are only weakly so. Steroids and glucocorticoids have been shown to induce SULTs in rats and humans [57]. For example, human SULT2A has been shown to be inducible by dexamethasone [190]. Transgenic, knockout, and humanized mice with a variety of NRs such as PXR, CAR, PPAR, AhR, and Nrf2 have been employed to study the function and regulation of UGTs. For example, experiments using PXR transgenic mice have helped to corroborate the regulation of UGT1A1 and UGT1A6 by PXR [44].

Given the potential for induction of the phase II DMEs as a result of their association with PXR and CAR, it is reasonable to assume their involvement in potential clinical drug–drug interactions. Indeed, induction of CAR (which regulates UGT1A1) by phenobarbital has been employed clinically to alleviate hyperbilirubimemia caused by the genetic disease Crigler–Najjar syndrome [191]. As discussed previously, these patients express very low levels of UGT1A1, an enzyme required for the metabolism of the endogenous compound bilirubin. However, drug–drug interactions due to induction are rare, and fewer than 20 drugs have been cited to date [192]. Examples of induction type drug–drug interactions include the interaction between rifampicin and zidovudine and rifampicin and lamotrigine [193,194].

Similar to drug-conjugating enzymes, transport proteins are regulated through PXR, CAR, FXR, and VDR [183]. Of these, PXR and CAR are the primary regulators of drug transport and are involved in the regulation of many of the human transport proteins including MDR1, MRP2, MRP3, MRP4, MRP5, BCRP, OATP1A2, OATP1B1, and OATP1B3 [195]. Research on the regulation of transport proteins continues to progress and the associated clinical implications have not been fully investigated. However, there are a few examples where clinical relevance of regulation of transport proteins has been demonstrated. For example, elimination of digoxin into bile has been increased by induction of MDR1 via PXR with rifampin, and the renal clearance of talinolol was increased after induction with carbamazepine [196,197]. These particular drugs were studied because they were not complicated by induction of DMEs and show that induction directly regulates the transport of drugs.

6.8 EFFECT OF DIETARY PHYTOCHEMICALS AND HERBAL SUPPLEMENTS ON NUCLEAR TRANSPORTERS, DRUG CONJUGATION, AND DRUG TRANSPORT

There are a number of dietary phytochemicals present in foods and herbal supplements, which have been shown to affect NRs, drug-conjugating enzymes, and transporters and result in food–drug or herb–drug interactions. In fact, clinically significant herb–drug interactions are becoming more common as more people are taking both herbal supplements and prescription drugs [198]. Herbal supplements that have been shown to affect the metabolism and transport of drugs include St. John’s wort, garlic, ginseng, milk thistle, and ginkgo [199]. St. John’s wort, which is used to treat depression, is one

of the most widely studied herbal medications. An extract of St. John's wort, *Hypericum perforatum*, has been shown to reduce the plasma exposure (AUC) of a number of drugs including midazolam, amitriptyline, nortriptyline, cyclosporine, and digoxin [199]. These drugs are primarily metabolized by CYP450 enzymes including CYP3A4 or in the case of digoxin, a substrate for P-gp. Protein levels of CYP3A4 and P-gp are modulated by PXR, hence St. John's wort appears to primarily exert its effect through PXR [200,201]. Similarly, the protein levels of the MRP2 transporter and GST-P 1 have been shown to be increased by St. John's wort. However, studies with St John's wort and examining its effect on NAT2 and UGTs have shown no interaction.

Garlic contains organosulfur compounds (e.g., diallyl sulfide, diallyl disulfide, and diallyl trisulfide) and has been shown to inhibit GST and induce both GST and UGT [202,203]. Ginseng contains seven ginsenosides (Rb1, Rb2, Rc, Rd, Re, Rf, and Rg1) as its active components and has been found to moderately inhibit P-gp [204]. Milk thistle, the active component of which is mostly silybin (a flavonolignan), has been shown *in vitro* to inhibit UGT1 and the transporters P-gp, BCRP, and OATP1B1 [199]. Clinically, however, the PK of most drugs studied thus far (indinavir, digoxin, rosuvastatin, etc.) have been shown to be unaffected by milk thistle, most likely because of the poor bioavailability (~1%) of its active components. [199]. Ginkgo, which has been widely studied for potential induction and inhibitory effects on the CYP450 enzymes, has not been as extensively studied in this regard for the phase II enzymes and transporters.

Dietary phytochemicals such as flavonoids and isothiocyanates present in food have demonstrated biological activity and have the potential to impact the NRs, DMEs, and transporters. Interest in phytochemicals present in cruciferous vegetables (e.g., broccoli and cauliflower) was piqued when researchers observed a connection between diets high in these vegetables and lower cancer rates in patients with liver, ovarian, lung, and cancers of the gastrointestinal tract [205]. One of the most active isothiocyanates is sulforaphane, which is found in high levels in cruciferous vegetables. Recent studies have demonstrated that sulforaphane exerts this effect as an antagonist of PXR, resulting in inhibition of PXR-mediated CYP3A4 expression and ultimately lower levels of CYP3A4 [206]. Given that it is believed that reactive oxidation metabolites formed by CYP3A4 may be the cause of some of these cancers, it is reasonable to assume that reduction of CYP3A4 enzyme levels would reduce the rate of cancer incidence [207]. The flavonoid quercetin that is present in high levels in foods such as fried onions has been shown to induce ABC transporters, such BCRP, as well as inhibit phase II metabolism of resveratrol [208]. Similarly, other dietary flavonoids and isothiocyanates have been shown to have inductive/inhibitory effects on PXR and BCRP as well as AhR, UGTs, GSTs, MRP-1, P-gp, and MRP-2 [199,209–211].

6.9 INTERSPECIES DIFFERENCES IN DRUG CONJUGATION, TRANSPORT, AND ELIMINATION

As a requirement for first time in man (FTIM) clinical studies, new drug entities (NDEs) must first undergo preclinical safety evaluation in other mammalian species (e.g., rats, dogs, and monkeys). In these studies, dose levels are chosen so that target organ toxicity can be determined and the plasma levels associated with the onset of toxicity at a given dose level are defined. Employing scaling factors, the results from these

studies are then extrapolated to select a safe starting dose for FTIM phase I clinical studies. Given the interspecies differences in physiology, anatomy, endocrinology, drug absorption, protein binding, expression levels of drug target, DMEs (phase I to III), and so on, the extrapolation from preclinical species to humans is one of the most challenging aspects of drug development. Lin [212] has shown that, in terms of describing differences that impact drug metabolism and elimination, it is appropriate to first consider the allometric relationship of blood circulation time (s) and total body weight (kg) between rats and humans. The allometric equation used for this calculation is $Y = aW^b$ (Y = physiological parameter, a = allometric coefficient, W = body weight, and b = the allometric exponent), which becomes $Y(\text{blood circulation time}) = 21 W^{0.21}$ [213]. Hence, if weights of 0.25 kg (rat) and 70 kg (human) are entered into the equation, the blood circulation times become 15 and 50 s, respectively, which means it takes roughly four times longer for blood to circulate in humans than in rats [212]. Similar calculations can be performed for hepatic and renal blood flow. Overall, this example demonstrates that for smaller species drug will circulate through organs more frequently and thereby is eliminated more quickly than in larger species. If this were the only factor implicated in interspecies differences then extrapolation between species would be relatively straightforward.

Walton *et al.* [214] has examined the magnitude of interspecies differences in exposure of drugs for which glucuronidation was the major metabolic pathway and demonstrated the necessity for risk assessments focused on fundamental processes that influence exposure. Species differences in glucuronidation, elimination, and metabolic pathways and the corresponding impact on drug exposure are clearly delineated. For example, for zomepirac the variation in $C_{\text{max}}/\text{dose}$ is 3200, 5700, 1700, and 2900 (ng/mL)/(mg/kg), respectively for human, rabbit, rat, and mouse. For lamotrigine, clearance ranges from 0.55 in humans to 12 mL/min/kg in dog and 14 mL/min/kg in rabbit (factors of 22 and 25, respectively). Species differences in metabolic and elimination pathways are quite profound. For example, in humans lamotrigine is cleared primarily in urine (85–94% of the dose) as the *N*-2- and *N*-5-glucuronides (86%). In dogs, lamotrigine is also cleared primarily in urine (53–67% of the dose) but as the *N*-2-methyl conjugate (80%). Finally, in rats 59–69% of the lamotrigine dose is cleared via the urine but mostly as the unchanged drug (57%). Species differences in the metabolism and elimination of AZT, oxazepam, morphine, lamotrigine, and paracetamol are summarized in Table 6.4. The predictability of other species as a model of biotransformation in man has been reported previously. For example, correct correlations to man have been found ~92% of the time in the rhesus monkey, 59% of the time in other nonprimate species, and only 41% of the time in the rat [215].

Species differences have also been noted for transport proteins. The canicular multispecific organic anion transporter (cMOAT) showed differences in *in vivo* clearance where transport values were highest in rat, followed by mouse, guinea pig, rabbit, and dog [217]. *In vitro* experiments using hepatocytes (fresh and cryopreserved) and fluorescent dye efflux assays have shown species differences between rats and humans for both MRP/Mrp function (rat elimination rate was higher) and BCRP/Bcrp (human elimination was higher). However, similar experiments on P-gp showed that although the elimination rate was functionally low for both species; no species differences in elimination rate due to P-gp were observed [218]. In a subsequent study, in which the levels of MRP2/Mrp2 were directly measured by LC/MS/MS in liver tissue, Li and coworkers found that the absolute amounts of MRP2/Mrp2 were highest in rat

TABLE 6.4 Species Differences in Drug Glucuronidation

Drug, OBA, Elimination Route	Human	Dog	Rat	Rabbit	Mouse

followed by monkey, human, and dog. Additionally, the tendency of rodent species to preferentially excrete compounds of lower molecular weight compared to humans has been discussed [219]. Species differences in biliary excretion are a primary factor accounting for differences in enterohepatic recirculation observed across species [174]. Additionally, interspecies variations in the intestinal microflora and their respective enzymes (e.g., β -glucuronidase and sulfatase) can cause significant differences in the rate and the extent of hydrolysis of drug conjugates [220]. Consequently, species differences in enterohepatic recirculation can impact the levels of metabolites observed [214,221].

It is clear that differences in metabolism, transport, and elimination can result in dramatically different exposures of drugs and their metabolites across species. Given that ADME and toxicity studies are first conducted in animals to gain an understanding of how a given NDE will behave in humans, great care should be taken in the planning, execution, and interpretation of data for these studies.

6.10 OTHER FACTORS AFFECTING THE CONJUGATION, TRANSPORT, AND ELIMINATION OF DRUGS IN HUMANS

Both intrinsic factors such as genetics, gender, age, race, organ impairment; and extrinsic factors such as diet, smoking, alcohol consumption, and concomitantly administered drugs can impact drug metabolism and transport and ultimately drug exposure and response.

Genetic factors and genetic diseases involving polymorphisms of drug-conjugating enzymes have been discussed and can clearly have a profound clinical impact. For example, genetic polymorphisms are estimated to influence the clinical outcome of 20–25% of all drug therapies [222,223]. Age has been shown to be more of a factor in the extent of UGT drug conjugation in children than adults [224]. For example, in neonates, the expression level of UGT1A6 is low but increases rapidly within the first month of birth, ultimately reaching adult levels after age of 10 [225,226]. Activity of UGT1A1 is low in neonates but increases to adult levels within three months of birth [227]. Similarly, UGT2B7 expression levels are low in infants but expression levels increase steadily and at 12–17 years of age are at 50% of adult levels [228,229]. In elderly patients, the conjugation of oxazepam, lorazepam, morphine, and lamotrigine have been reported as being reduced resulting in an apparent age-related reduction in clearance [230–233]. Overall, most studies have shown that UGT activity or the activity of other drug-conjugating enzymes is not extensively impacted in older individuals who are over 65 years old [229,234–236]. Recent data obtained from human liver banks have supported these findings for UGT enzymes [229]. In terms of other conjugation enzymes, *N*-methyltransferase and most SULTs are at adult levels in newborns [236]. In fact, sulfonation compensates for glucuronidation in neonates and children as evidenced by the higher levels of sulfate conjugates observed for some drugs (e.g., salicylamide) [225]. Expression levels of GSTs are higher in neonates compared to adults while glycine conjugation is deficient in neonates [236].

Gender differences have been implicated in the variation of phase II metabolism for several drugs [223,237]. One of the most notable involves conjugation of the common over-the-counter (OTC) drugs aspirin and acetaminophen (paracetamol). Men produce higher levels of glycine and glucuronic acid conjugates of aspirin than women, which may explain its higher bioavailability in women [238]. Similarly, acetaminophen clearance rates in men were found to be 22% higher than in women because of higher levels of UGT activity in men [239]. Additionally, glucuronidation of *S*-oxazepam was 65% higher in livers from male donors versus female donors [231,240]. In recent NDA applications, it has been shown that in around 7% of these filings, there is at least a 40% difference in PK between men and women [241].

There have not been extensive investigations on alcohol consumption and drug conjugation. From data collected from human liver banks, alcohol consumption has been associated with high levels of glucuronidation for UGT1A probes but did not appear to

affect other UGT isoenzymes (e.g., UGT2B7 or UGT2B15) [229]. Studies conducted, which investigate the effect of alcohol on glucuronidation, have been inconsistent with some studies showing an effect and others showing no effect [229]. The findings from studies conducted on cigarette smoking yielded similar conflicting findings [229]. Little or no data are available on the effects of alcohol consumption or smoking on other drug-conjugating enzymes. Although smoking does not appear to have much of an impact on the extent of drug conjugation, recent studies have been conducted that correlate polymorphisms of NAT1 with an increased risk of pancreatic cancer [242]. The results have shown that women who are heavy smokers and carry the NAT1*10 allele have a fourfold higher risk of developing pancreatic cancer presumably because of the decreased ability to metabolize the suspected pancreatic carcinogens, *N*-nitroso and aromatic amines found in cigarette smoke.

6.11 SUMMARY AND FUTURE PERSPECTIVES

Over the last two decades of research, significant progress has been made in our understanding of drug conjugation and transport. During this time, it has become clear that the coordination of conjugation metabolism, conjugate transport via transport proteins, and elimination pathways are inexorably linked and complex. Therefore, changes in one could dramatically impact drug exposure and elimination, and hence the efficacy/toxicity of a drug. One also has to consider the role of NRs in the regulation of drug-conjugating enzymes and transport proteins as chemical inducers and genetic variations in NRs as having a potential effect on drug exposure. Additionally, intrinsic and extrinsic factors have an impact on the conjugation enzymes, transport proteins, and NRs. The human body has a remarkable ability to protect itself from potentially harmful chemicals. As such, these protection mechanisms have greatly impeded our ability to make safe and efficacious drugs. Hence, in order to improve our ability to optimize drug development, a deeper understanding of the mechanisms of drug conjugation, transport, and NRs and their interdependency is required.

7.1 INTRODUCTION

Glucuronidation is one of the most common pathways of conjugative metabolism. It is responsible for the elimination of ~40–70% of all drugs that are metabolized via phase II conjugation [1–6]. The reaction is catalyzed by a family of uridine 5'-diphosphate-glucuronosyltransferases (UGTs) and involves condensation of a pharmacologically active drug molecule (or its phase I product) or endogenous substances with the activated form of glucuronic acid, uridine-5'-diphospho- α -D-glucuronic acid (UDPGA) (Fig. 7.1). The UGT enzymes recognize a multitude of functional groups including aromatic and aliphatic alcohols, carboxylic acids, amines, and the free sulfhydryl moiety. The outcome is the formation of an *O*-, an *N*-, a *C*-, or a *S*-glucuronide [3]. Examples of endogenous substrates for UGT include bilirubin, steroid hormones, thyroid hormones, bile acids, and fat-soluble vitamins. Similarly, numerous exogenous therapeutic agents belonging to various classes including opioids, analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), and anticonvulsants are also glucuronidated (Fig. 7.2). Molecules that possess both the hydroxyl and carboxyl groups such as mycophenolic acid (MPA) or diflunisal can be transformed to both types of glucuronide conjugates.

Figure 7.1 Scheme showing glucuronidation reaction. UDPGA, uridine-5'-diphospho- α -D-glucuronic acid; UGT, uridine 5'-diphosphate-glucuronosyltransferase.

Figure 7.2 Some examples of endogenous compounds and drugs that undergo glucuronidation.

The introduction of a carbohydrate moiety containing a readily ionizable carboxy group ($\text{pK}_a = 3\text{--}4$) renders the corresponding conjugates water soluble, thus enhancing their excretion renally. In some cases, the polar conjugates exhibit good substrate properties for efflux proteins/transporters that result in the excretion of these conjugates into the bile [6].

7.2 CLASSIFICATION

Like cytochrome P450s (CYPs), human UGTs are a superfamily of enzymes. The mammalian UGT gene superfamily currently has 117 members that are divided into four families, UGT1, UGT2, UGT3, and UGT8 [7,8]. Of these four families, UGT1 and

UGT2 use UDP glucuronic acid to glucuronidate endogenous and exogenous chemicals. UGT8, in contrast, uses uridine 5'-diphosphate (UDP) galactose to galactosidate ceramide, an important step in the synthesis of glycosphingolipids and cerebroside. The function of the fourth family, UGT3, is unknown at this time. However, studies show that this enzyme catalyzes the transfer of *N*-acetylglucosamine from UDP *N*-acetylglucosamine to ursodeoxycholic acid (3 α , 7 β -dihydroxy-5 β -cholanoic acid). Of all the families, the UGT1 and UGT2 families are more relevant to humans owing to their role in metabolizing several xenobiotics that include drugs, environmental toxicants, carcinogens, and more. The UGT1 family consists of nine isoforms: UGT1A1, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, and 1A10 whose catalytic functions have been well characterized (Table 7.1). Eight of these isoforms are clinically relevant and are involved in the metabolism of several drugs. The isoforms in the UGT1 family are encoded by human *UGT1 gene* that is located on chromosome 2 at locus 2q37 with common exons 2–5 and at least 13 unique varieties of exon 1 [7]. Thus, all isoforms have the same carboxy termini but different amino-terminal domains. The human UGT2 family is subdivided into two subfamilies: UGT2A and UGT2B and are clustered on chromosome 4p13 [7]. As the UGT1A family, exon-sharing is also seen with the 6-exon UGT2A1 and UGT2A2 gene families. However, UGT2A3 and the UGT2B subfamilies are encoded by separate genes. The UGT2B family is composed of the following functional proteins: UGT2B4, 2B7, 2B10, 2B11, 2B15, 2B17, and 2B28 (Table 7.1). Even though all UGT isoforms in this family are involved in the metabolism of compounds, isoforms UGT2B7 and 2B15 are more important clinically since they are involved in catalyzing the conjugation of some important drugs such as morphine, diclofenac, ezetimibe, entacapone, or oxazepam (Table 7.2). Overall, the UGT enzymes in each family share at least 50% homology in their DNA sequences, whereas enzymes in each subfamily share at least 60% homology in their DNA sequences.

7.3 SUBSTRATE SPECIFICITY

Unlike the CYPs, the determination of substrate specificity for different UGTs is complicated by the overlapping substrate activities (i.e., one substrate is metabolized by several isoforms) and broad substrate specificity where one isoform glucuronidates a wide range of substrates [9–11]. It is important to note that even though one compound may be metabolized by several UGTs, the efficiencies and turnover rates may vary among the isoforms. For instance, 4-nitrophenol and 1-naphthol or the coumarin derivative, 4-methylumbelliferone (4MU), is glucuronidated by most UGT proteins, but these compounds are catalyzed most efficiently by the UGT1 proteins, with the exception of UGT1A4. Tables 7.2 and 7.3 summarize the substrates that are metabolized by UGT1A and UGT2B families, respectively.

A comprehensive list of substrates for various UGT isoforms can also be found in the review by Kiang *et al.* [12]. Despite the overlapping substrate selectivity, some substrates have been identified that are more selective toward a particular UGT isoform. For example, the endogenous substance bilirubin is predominantly (if not solely) glucuronidated by UGT1A1. However, given the technical difficulties such as the light-sensitive nature of the compound and difficulty in assaying owing to high protein binding and poor recovery, it is not recommended for use as a probe for UGT1A1. Other probes for UGT1A1 include etoposide (almost exclusively glucuronidated by

UGT1A1) and β -estradiol. It should be noted that UGT1A3 also contributes to glucuronidation of β -estradiol [11]. Similarly, trifluoperazine has been used as a probe substrate for UGT1A4. Other compounds that have been regarded as probe substrates for different UGT isoforms are listed in Table 7.4 [10,11,13]. Some of these compounds have been considered as possible probes for individual UGT isoforms because they are the major isoforms responsible for the glucuronidation of these compounds in tissue fractions *in vitro*. Since the isoform selective substrates for UGT are limited, reaction phenotyping of UGT substrates is most commonly done using recombinant isoforms. Sometimes, a correlation analysis in human liver microsomes (HLMs) has been used to facilitate the identification of UGT isoforms [11].

7.4 TISSUE DISTRIBUTION

In the cell, the UGT enzymes are located in the lipid bilayer of the endoplasmic reticulum along with the CYP isoforms. This unique location of UGTs next to CYPs helps in converting the CYP-mediated oxidative products to more water soluble compounds, in addition to parent drugs, and helps in modulating concentrations of the parent drug and its phase I metabolites in circulation and in various tissues. To understand the clinical implications mediated by the UGT enzymes, it is important to know the tissue distribution and the content of these enzymes in specific tissues, in addition to the drug/metabolite concentrations. The reported information on tissue distribution of the most clinically relevant isoforms of UGT partially parallels that described for CYP in that the activities are highest in organs/tissues that are responsible in excreting the chemicals out of the body such as the liver and kidney. Table 7.1 also summarizes the tissue distribution of all known isoforms of UGT. The UGT isoforms primarily expressed in the liver include UGT1A1, 1A3, 1A4, 1A6, 1A9, 2B4, 2B7, 2B10, 2B11, 2B15, 2B17, and 2B28 [14], while mRNAs of UGTs 1A3, 1A6, 1A8, 1A9, 1A10, 2B7, and 2B17 have been detected in the kidney tissues [3,5,15,16]. Studies in the past two decades have shown that UGTs are also present in the gastrointestinal tract including gastric tissue, small intestine, and colon where they can also affect the absorption of drugs [17]. The following UGT mRNAs have been detected in the small intestine:

TABLE 7.4 Potentially Useful Probe Substrates of Human UGTs [10,11,14]

UGT Isoforms	Substrates
UGT1A1	Bilirubin; etoposide, β -estradiol
UGT1A3	<i>R</i> -Lorazepam
UGT1A4	Trifluoperazine; lamotrigine
UGT1A6	Serotonin
UGT1A8	Raloxifene
UGT1A9	Profolol; mycophenolic acid
UGT2A1	(-)-Citronellol
UGT2B4	Hydrodeoxycholic acid
UGT2B7	Zidovudine, morphine
UGT2B15	<i>S</i> -Oxazepam; <i>S</i> -lorazepam
UGT2B17	Dihydrotestosterone

UGT1A1, 1A3, 1A4, 1A6, 1A8, 1A10, 2B4, 2B7, 2B10, and 2B15, and the colon contains 1A1, 1A3, 1A4, 1A6, 1A8, 1A9, 1A10, and 2B7. In addition, UGT1A and 2B isoforms are also differentially expressed in various tissues including the olfactory epithelium, ovary, lung, mammary gland, adipose tissue, testis, and prostate. For example, UGT1A8 and 1A10 are exclusively expressed in the GI tract but not detected in the liver. Likewise, UGT1A5, 1A7, 1A10, and 2B28 are expressed in high levels in the GI tract relative to the liver [18,19]. Similarly, current literature evidence indicates that UGT2A1 is mainly expressed in the nasal epithelium [20]. Likewise, the UGTs from the UGT2B family are abundantly expressed in steroid-sensitive tissues such as the prostate (UGT2B10, 2B15 and 2B17) or mammary tissue (UGT2B11 and 2B28) [12]. Other tissues where glucuronidation can occur include the brain and placenta [12]. The factors that govern this tissue specificity of UGT expression remain largely unknown.

7.5 ROLE OF UGTs IN ABSORPTION

Glucuronidation is one of the important enzymatic processes that can contribute to presystemic or “first-pass” drug metabolism. For many years, hepatic metabolism has been recognized as the primary organ that impacts oral bioavailability of drugs. However, the intestine is now recognized as an important contributor in impacting oral bioavailability/absorption of drugs via glucuronidation, thereby altering their systemic exposure [17]. Drugs that fall in this category include gemfibrozil, diclofenac, MPA, raloxifene, ezetimibe, zidovudine, resveratrol, morphine, and lamotrigine (Fig. 7.2). Following oral administration, these drugs are rapidly absorbed. However, the plasma concentrations of the parent are typically found to be lower compared to their corresponding phase II metabolites such as glucuronide or sulfate conjugates. Although the liver and intestine are thought to be responsible for this extensive first pass, mechanistic *in vivo* and *in vitro* studies have indicated that contribution of the intestine in the glucuronidation for most of these drugs is greater than that by the liver. For instance, in humans, the absolute oral bioavailability of raloxifene, a selective estrogen receptor modulator indicated for the treatment of osteoporosis and breast cancer prevention, is only 2% at a dose of 60 mg once daily [21]. This drug is extensively metabolized via glucuronidation with <1% of the parent being excreted in human urine. Two conjugates have been detected in plasma following oral administration of raloxifene (Fig. 7.3). Recent *in vitro* studies suggest that this drug is primarily metabolized in the small intestine by UGT1A8 and 1A10, indicating that presystemic intestinal glucuronidation has a significant impact on the oral bioavailability of raloxifene [22]. Furthermore, kinetic evaluation of intestinal glucuronidation on oral bioavailability (F) was assessed using reported human data of raloxifene by determining the fraction absorbed (F_f), presystemic intestinal availability (F_{pg}), and presystemic hepatic availability (F_h) [23]. This analysis revealed that F_{pg} was 5.4%, whereas F_f and F_h were 63% and 59.3%, respectively. Lower F_{pg} value compared to F_h suggested that intestinal glucuronidation exerts a greater impact on oral bioavailability than hepatic glucuronidation.

Similarly, studies with ezetimibe, a new class of cholesterol-lowering agent, have also shown that its poor exposure in systemic circulation is primarily owing to extensive intestinal first-pass metabolism of the compound [24]. The main circulating metabolite of this drug in human plasma is the phenolic glucuronide conjugate of

Figure 7.3 Glucuronidation of raloxifene to 4'-glucuronide and 6-glucuronide.

Figure 7.4 Glucuronidation of ezetimibe.

ezetimibe (Fig. 7.4) [25]. The primary UGTs involved in the metabolism of ezetimibe were UGT1A1, 1A3, and 2B15. However, intrinsic clearance values ($V_{\max}/K_m$ ratio) for glucuronide formation were similar between liver and the intestine, indicating that the contribution of intestine in clearing the compound was significant. This was confirmed when 1-min intraduodenal delivery of ezetimibe resulted in glucuronide as the major metabolite in portal plasma of rats [26].

Figure 7.5 Metabolic scheme of irinotecan.

Intestinal UGTs may affect the biological and adverse effects of drugs on the enterocytes by facilitating the inactivation of drugs and by lowering their intracellular concentrations. For instance, the effect of MPA on intestinal cell proliferation is potentially reduced as a result of its glucuronidation, thereby reducing its concentration in the target cells [27,28]. Similar phenomenon has also been observed on the antiproliferative effect for the antineoplastic agent irinotecan (Fig. 7.5) [29,30]. Following an intravenous (IV) dose of irinotecan, this drug undergoes hydrolysis by carboxyesterases to form the active metabolite SN38, a potent topoisomerase inhibitor that causes disruption of DNA replication. SN38 is then eliminated primarily by UGT1A1-mediated glucuronidation (Fig. 7.5). *In vitro*, an inverse correlation has been observed between SN38 concentration and its antiproliferative effect in colorectal cancer cells [29,30]. It is possible that glucuronidation of SN38 may reduce the intracellular concentration of this compound, thus attenuating its antiproliferative effect.

7.6 BIOACTIVATION BY UGTS

7.6.1 Toxicological Implications

While glucuronidation is a process that facilitates inactivation, detoxification, and elimination of compounds from the body, there are instances where this pathway could potentially produce metabolites that elicit adverse drug reactions by damaging intracellular proteins. On the other hand, glucuronide conjugates may retain or have enhanced or different pharmacological activity compared to the parent drug such as the metabolites formed by CYPs [31,32].

From a toxicological point of view, glucuronide conjugates can elicit their toxicity in two ways. The first involves a covalent interaction of a glucuronide conjugate with macromolecules such as the proteins or nucleic acids owing to the inherent chemical reactivity of some glucuronides. Such an interaction can result in a macromolecular adduct that could interfere with the normal functioning of the cell systems or, alternatively, induce an immune response against the drug protein adduct. Another

“indirect” way by which the glucuronides can educe toxicity is via the interaction of the conjugates with transporters. Most glucuronide conjugates are substrates for MRP2 efflux transporters due to the presence of the anionic glucuronic acid moiety. Thus, glucuronidation can act as a pathway that helps to shuttle proximate or ultimate carcinogens and/or toxins to the biliary-intestinal tract, kidney, and bladder and facilitate organ specific toxicity [33].

Although most glucuronide conjugates are chemically stable, the conjugation of a glucuronic acid moiety with hydroxamate or carboxylate groups is of toxicological importance owing to their inherent chemical reactivity. Of greater clinical significance among the two are the acyl glucuronides, which are formed via esterification of compounds containing carboxylic acid groups and glucuronic acid (Fig. 7.1). This is because several carboxylic acid containing compounds are primarily metabolized by UGTs. Some substrates with a carboxylic acid group include endogenous compounds such as bilirubin, leukotrienes bile acids, fatty acids, and retinoic acid and drugs such as nonsteroidal anti-inflammatory (NSAIDs), hypolipidemic (“fibrates”), hypoglycemic (“glitazars”) agents, immunosuppressants (MPA), diuretics (furosemide), and anticonvulsants (valproic acid) (Fig. 7.2). In some cases, even if a compound is not a carboxylic acid, it may be metabolized to a carboxylic acid through phase I metabolism, which may then undergo glucuronidation, as observed for celecoxib (Fig. 7.6).

The chemical reactivity and, therefore, the covalent bond formation between these conjugates and the proteins are attributed to the ester functionality in acyl glucuronides. These molecules can react with macromolecules by two possible ways. The first one involves a simple displacement of the glucuronosyl group by nucleophilic moieties in the macromolecules that results in acylation of the protein with the aglycone (Fig. 7.7a). This is known as the *transacylation reaction* [31,34]. Proteins with nucleophilic groups on the amino acids such as the ϵ -amino of the lysine, the phenolic hydroxyl group of tyrosine, and the thiol of cysteine are more prone to these kinds of reaction and result in the acylation of the proteins. An alternate mechanism involves an intramolecular rearrangement as depicted in Fig. 7.7b. This so-called glycation reaction differs from the transacylation reaction in that both the aglycone and the sugar group are present in the final adduct. This mechanism involves an acyl migration in which the acyl group rearranges from its initial C-1 position on the glucuronic acid to position C-2 and subsequently to C-3 or C-4 (Fig. 7.7b). The mechanism is proposed to involve the nucleophilic attack by hydroxyl on the adjacent carbon resulting in the formation of β -glucuronidase resistant glucuronides. This intramolecular rearrangement exposes the hemiacetal group of the sugar moiety and leads to the transient ring opening to form

Figure 7.6 Metabolism of celecoxib to acyl glucuronide via oxidation by P450.

Figure 7.7 (a) Transacylation of proteins by acyl glucuronides. (b) Migration of acyl glucuronides and covalent binding to proteins (glycation).

the open chain aldehyde intermediate. The corresponding aldehyde group can then condense with amino groups on the lysines or nucleic acids to form imines that undergo a rearrangement (amadori rearrangement) to yield the final adduct, a more stable 1-amino-1-deoxyketose structure, which retains both the sugar and the aglycone. Both these mechanisms have been discussed in several reviews over the years [31,32,35–43].

Although no definitive relationship has been established, it is now accepted that covalent binding to amino acid residues of macromolecules and bases of nucleic acids often can result in hypersensitivity reactions, organ toxicities (hepatic or renal toxicities), mutagenesis, or carcinogenesis. An unacceptably high incidence of significant adverse drug reactions has been reported for drugs containing carboxylic acid. Several drugs with this group have been withdrawn after introduction to the market or have otherwise been associated with liver toxicity (Table 7.5). One of the earliest documented examples of a carboxylic acid compound involved in severe toxic reactions is that of the NSAID ibufenac. Ibufenac is a structural analogue of ibuprofen and was marketed in the late 1960s. Within a few years, ibufenac was withdrawn from the market. The compound is primarily metabolized to an acyl glucuronide and is shown to covalently bind to proteins at least, *in vitro* [44]. Similarly, Smith *et al.* [45] have shown that zomepirac acyl glucuronide reacts with human serum albumin (HSA) *in vitro*. An *in vivo* study in human volunteers showed a linear correlation between the area under the plasma concentration-time curve (AUC) of zomepirac acyl glucuronide (but not zomepirac itself) in plasma and the amount of zomepirac covalently bound to plasma proteins [45]. This suggests that zomepirac acyl glucuronide is responsible for forming covalent protein adducts. The mechanism for binding of zomepirac to HSA is mediated by both transacylation and Schiff-base formation with lysine residues in the protein, which undergoes an amadori rearrangement leading to a stable adduct described above [46,47]. Similar *in vivo* results have been reported for other structurally related NSAIDs such as tolmetin, diclofenac, benoxaprofen, and ticrynafen [32,37,43,48]. The formation of acyl glucuronide is a primary metabolic pathway for all the above-mentioned compounds. Furthermore, all these acyl glucuronides have been shown to undergo acyl migration and amadori rearrangement described above to some degree. In addition to

TABLE 7.5 Carboxylic-Acid-Containing Drugs Withdrawn from the Market Because of Toxic Effects

Drug	Structure	Toxicity

Drug	Structure	Toxicity
Temafloracin		Severe anaphylaxis
Ticrynafen		Hepatotoxicity
Zomepirac		Pulmonary toxicity

HSA, the acyl glucuronides have also been shown to react with other proteins. For instance, diclofenac, which is still in use in most of the world today, has been associated with hepatotoxicity as well as immune mediated toxicity. Work by Kretz-Rommel and Boelsterli as well as others has shown that the *in vitro* covalent binding of diclofenac to hepatocellular proteins including dipeptidyl peptidase IV (DPP IV) was dependent on diclofenac acyl glucuronide formation [49,50]. Similar covalent binding to DPP IV and tubulin has been shown for zomepirac as well [51,52]. In another instance, DNA is a target for the acyl glucuronide conjugate of gemfibrozil. Incubations of gemfibrozil acyl glucuronide conjugate with DNA resulted in the formation of covalent adducts and mutagenesis [53].

As mentioned earlier, transporter-mediated excretion of glucuronide conjugates is another means by which these metabolites can mediate organ or intestinal toxicity. In this process, efficient canalicular transporter(s) mediate extrusion of toxic or reactive glucuronide conjugates from liver into the biliary tract and the gastrointestinal lumen [32,38]. This results in high concentration of these toxic conjugates at the distal sites and subsequently may elicit toxicity. For instance, several NSAIDs are known to cause acyl-glucuronide-mediated damage to the small intestine. Similarly, MRP-2-mediated efflux transporter of glucuronide conjugates of carcinogens from the liver (where they are formed) can result in high exposure of the toxins and carcinogens via their local regeneration by β -glucuronidase catalyzed hydrolysis of the β -glucuronides. Thus, the combined effects of UGTs and MRP2 may have toxicological consequences by intracellular detoxification of the compounds, efflux of these compounds via the MRP2-dependent translocation of the conjugate to the distal site, and regeneration of

the aglycone [54,55]. Coupling of glucuronidation with the transporter-mediated effect of the conjugate has been implicated in the intestinal toxicity of irinotecan [32,56,57]. Major dose-limiting toxicities of irinotecan (Fig. 7.5) are severe diarrhea and myelosuppression. The major route of excretion of the aglycone and its glucuronide conjugate (SN38 glucuronide) is the bile and feces following an IV administration. Although the concentrations of SN38 glucuronide in the bile are equal or greater than the aglycone, a significant amount of SN38 is found in the feces compared to its glucuronide conjugate. This is consistent with the β -glucuronidase-mediated hydrolysis of the metabolite in the gut. Several studies have shown that SN38 glucuronide is a substrate of MRP2 and that its excretion into the bile is mediated via efflux of the glucuronide by this transporter. Taken together, although glucuronidation acts as a detoxification pathway of SN38 *in vivo*, its toxicity (delayed diarrhea) is mediated via its transport of the glucuronide (via the bile) by MRP2 to the GI tract coupled with regeneration of the aglycone at this site by β -glucuronidase.

Another way that the glucuronide conjugates can elicit toxicity is by indirectly increasing the concentrations of the parent drug in systemic circulation. This has been commonly observed in NSAIDs where the acyl glucuronides are the major metabolites (as described previously). Since the ester linkage in these glucuronide conjugates is prone to a nonenzymatic hydrolytic cleavage back to the aglycone under mild alkaline conditions, a situation where there is an impairment of the elimination pathway of acyl glucuronides could result in “futile cycling” of the parent drug [37]. This “reversible metabolism of acyl glucuronide” can have potential clinical implications especially in patients with decreased renal clearance. When an acyl glucuronide is a primary metabolite of a drug, renal impairment will affect the elimination of the glucuronide conjugate via the urine. The decreased renal elimination of the glucuronide conjugate can result in its hydrolysis back to the parent drug and, therefore, decrease the apparent metabolic clearance of the aglycone and increase its systemic exposure. For instance, benoxaprofen was withdrawn from the market because of reports of renal impairment and cholestatic liver toxicity and a high fatality rate. The drug has a relatively long half-life in the human body (33 h), with the majority of the dose eliminated by renal excretion as the acyl glucuronide. Although the exact reason for the observed toxicity still remains uncertain, it has been speculated that impaired renal excretion could lead to increased systemic and tissue drug load, causing cholestasis and renal injury, which would further decrease excretion of the drug and eventually cause toxicity. This has been observed for other drugs including clofibrilic acid, diflunisal, indoprofen, and ketoprofen.

Although uncommon, in recent years, reports of inhibition of CYPs by acyl glucuronides have also appeared in the literature. A classic case where a glucuronide conjugate has led to inhibition of a CYP enzyme and, therefore, has been implicated in drug–drug interactions (DDIs) is that of gemfibrozil [58,59]. Although gemfibrozil has been shown to be a weak inhibitor of CYP2C8, gemfibrozil-1-*O*- β -glucuronide (GEM-1-*O*-gluc) metabolite was found to be a more potent inhibitor of CYP2C8 activity. Furthermore, Ogilvie and coworkers found that preincubation of the inhibitor lowered the IC_{50} for inhibition of CYP2C8-mediated paclitaxel metabolism from 24 to 1.8 μ M *in vitro*. Additional studies conducted to understand the mechanism of inactivation of the CYP enzyme by glucuronide conjugate suggested that it was covalently linked to the prosthetic heme group during catalysis. The mechanism involved oxidation of the GEM-1-*O*-gluc to a benzylic radical intermediate that partitioned between oxygen

rebound and addition to the γ -meso carbon of heme [59]. Formation of the GEM-1-*O*-gluc-heme adduct most assuredly would block additional substrates from accessing the catalytic heme center of CYP2C8 and result in the observed mechanism-based inhibition.

7.6.2 Pharmacological Implications

Although many pharmacologically active metabolites are known to be formed through oxidative or reductive processes (phase I reactions), glucuronide conjugates can also interact with receptors and impart biological effects through noncovalent interactions with the receptor. Active glucuronide conjugates may have equivalent, and in some cases, superior pharmacological activity and can, therefore, contribute to the overall pharmacological effect of the parent drug. Since the overall efficacy of a drug can be augmented by the formation of active metabolite(s), characterization of the isozymes that catalyze the formation of these conjugates is extremely important.

Morphine is a classic example where a glucuronide conjugate contributes to the pharmacological activity of the parent [60]. Morphine is primarily eliminated by glucuronidation, a process that results in phenolic 3-OH glucuronide and the alcoholic 6-OH glucuronide (Fig. 7.8). Only the 6-OH glucuronide is active and displays full agonist properties at the μ -opioid receptors. Humans convert 10%–20% of an administered morphine dose to the 6-OH glucuronide and this reaction is catalyzed by UGT2B7. Since the conjugate is more potent than the parent and accumulates in plasma at concentrations greater than that of morphine during chronic treatments, it is considered to contribute significantly to the clinical efficacy during chronic morphine therapy.

Besides morphine, several other drugs also have pharmacologically active glucuronide conjugates. For instance, the phenolic glucuronide conjugate of ezetimibe has been shown to be equally potent toward the intended pharmacological target

Figure 7.8 Metabolic schemes of morphine and codeine.

(Fig. 7.4) [26,61,62]. Similarly, the hypocholesterolemic effect of S-8921, a novel inhibitor of an ileal apical sodium-dependent bile acid transporter (ASBT/SLC10A2), is attributed to its glucuronide conjugate (S-8921G) that is formed in the intestine (Fig. 7.9) [62,63]. Conversion of S-8921 to its glucuronide conjugate is mediated by several UGTs, particularly UGT1A1, 1A3, 1A8, 1A9, and 1A10. This glucuronide conjugate is a 6000-fold more potent inhibitor of an ileal apical sodium-dependent bile acid transporter (SLC10A2) than the parent compound. Similarly, the glucuronide conjugates of retinoic acid and retinol have demonstrated enhanced retinoid activity relative to the parent compound [31].

7.6.3 Prevention of Toxicity by Glucuronidation

Even though some glucuronide conjugates have been implicated to be associated with eliciting the toxicity of a drug, studies have shown that glucuronidation mostly play an important role in detoxication of carcinogens and hepatotoxicants [64]. Differential expression of UGTs in specific tissues can change the metabolic ratio between bioactivation and detoxification. A change favoring bioactivation can render increased susceptibility to toxic effects and vice versa. Thus, the knowledge of glucuronidation capacity of the UGTs and the type of UGTs involved in the catalysis can provide an increased understanding of the bioactivation/detoxification balance for these toxicants. For instance, many phenolic compounds are prone to oxidative bioactivation via CYP or prostaglandin H synthase to highly toxic electrophilic and/or free radical reactive intermediates that can damage cellular macromolecules (e.g., DNA, protein, and lipids) and/or enhance oxidative stress. This is also true for many compounds where aromatic hydroxylation is the primary pathway of metabolism. However, most often, high efficiency of the glucuronidation process in eliminating these compounds deters them from undergoing metabolic oxidation. Thus, glucuronidation and elimination of the xenobiotic and/or its stable metabolite serves as a toxicological gatekeeper, directing metabolism away from bioactivation. Generally, genetic predisposition of subjects, which can result in low expression of UGTs that are primarily involved in the metabolism of these compounds, drives the metabolism of these compounds toward bioactivation and generation of reactive metabolites [65]. A classic case illustrating this is that of acetaminophen, which is hepatotoxic and nephrotoxic at high doses.

Figure 7.9 Structure of S-8921.

Figure 7.10 Metabolic activation and glucuronidation of acetaminophen.

This widely used analgesic undergoes metabolism primarily via UGT1A1-mediated glucuronidation of the phenolic group and CYP-mediated oxidation to a quinone imine (NAPQI) (Fig. 7.10). The latter has been shown to covalently bind to proteins and this has been implicated in the hepatotoxicity and renal toxicity observed in patients. Studies using intravenous drug administration in humans with a hereditary UGT1A1 deficiency showed reduced glucuronidation of acetaminophen and, conversely, enhanced bioactivation as determined by the formation of glutathione conjugates of acetaminophen, which was a marker for the formation of NAPQI intermediate [66,67]. Similar results were observed in mutant Gunn and RHA rats, which lack all UGT1A enzymes. These animals had reduced acetaminophen glucuronidation, enhanced CYP-catalyzed bioactivation of acetaminophen and covalent binding to hepatocellular proteins, and enhanced hepatocellular centrilobular and renal cellular necrosis.

A similar conclusion can be made in the case of raloxifene that is readily bioactivated to electrophilic intermediates and is a potent inactivator of CYP3A4. Despite these *in vitro* findings, in humans, no major raloxifene-related toxicities have been linked to bioactivation of this drug. It is hypothesized that this disconnect between safety of raloxifene and its *in vitro* bioactivation is attributed to its presystemic metabolism via glucuronidation. The effect of glucuronidation on the covalent binding of raloxifene to liver microsomal proteins has been demonstrated [68]. These *in vitro* studies with [^{14}C]raloxifene suggest that the covalent binding to microsomal protein is significantly decreased in the presence of glucuronidating processes. These results support the notion that intestinal glucuronidation of raloxifene limits its bioactivation by liver in humans.

7.7 PREDICTION OF HUMAN CLEARANCE FOR COMPOUNDS CLEARED VIA GLUCURONIDATION

Since a number of drugs and early candidates are primarily cleared via glucuronidation, the ability to predict human metabolic clearance for compounds that are primarily

cleared by this route can be an asset in early discovery and development of drugs. This not only assists in the selection of a candidate with good PK properties but also gives an early assessment of the dosing regimens for clinical studies. The ready availability of HLMs, isolated hepatocytes, and recombinant enzymes has made it possible to conduct kinetic studies that enable determination of microsomal intrinsic clearance (CL_{int}), which can be further extrapolated to determine the CL_{int} in the whole liver and eventually human clearance (CL_h) and extraction ratio [69–72]. Although this approach has proved useful for many CYP-catalyzed reactions, drug clearance predictions using microsomal data have tended to under-predict *in vivo* clearance for compounds that are primarily eliminated via glucuronidation [11,73–79]. Methods for studying glucuronidation in microsomes have varied considerably, which has led to questions about the suitability of this *in vitro* system to accurately predict the glucuronidation clearance [79].

Although reasons for this underestimation are unclear, many experimental variables have been shown to influence the scaling of *in vitro* glucuronidation clearance to an *in vivo* setting. First and foremost among these factors is the influence of localization of the UGT in comparison to CYPs. The UGT is localized on the luminal side of the microsomal membrane and this may give rise to “diffusional” barriers. Several methods have been introduced to circumvent this problem, including the use of the pore-forming agent alamethicin or a detergent or sonication treatment [80,81]. The use of alamethicin has proved very useful and recently become a standard practice to assess glucuronidation reactions and kinetics. More recently, the general implications on the suitability of alamethicin-activated microsomes for predicting the clearance for compounds with parallel CYP and UGT pathways have been described [75]. The results of this study suggested that alamethicin did not affect CYP activity since the sum of the individual CL_{int} values from the individual cofactor studies were approximately equal to the combined cofactor CL_{int} for all of the drugs investigated. In addition, experimental conditions can also be another reason for the failure of the microsomal procedures to predict glucuronidation clearance. Incubation components are known to modulate microsomal UGT activity, and therefore the kinetics of drug glucuronide formation can vary with experimental conditions such as buffer type, pH, and ionic strength, the presence of $MgCl_2$, and detergent used [11].

An additional factor that may contribute to the observed underprediction is the influence of nonhepatic UGTs to the metabolism of the evaluated drug, which typically is not included in the current methods of *in vitro* to *in vivo* scaling. As discussed previously, some UGTs, notably UGT1A7, 1A8, and 1A10 are expressed in the gastrointestinal tract [17]. Similarly several UGTs are highly expressed in the kidney [82]. Several well-known drugs are metabolized by the intestinal or renal UGTs (e.g., pro-folol, raloxifene, or troglitazone) [22,83,84]. Hence, the *in vivo* CL_{int} values scaled from incubations with HLMs may be underestimates or erroneous for compounds that are primarily metabolized by nonhepatic UGT enzymes. Comparison of CL_{int} values derived using liver, kidney, and intestinal microsomes may provide important insights into the relative contribution of these organs to the overall CL and/or first-pass extraction [85]. For instance, scaled intestinal CL_{int} , UGT (per g tissue) was six- and ninefold higher than hepatic for raloxifene and troglitazone, respectively [71,86]. Hence, it may be necessary to include this factor in the equation to obtain a more accurate prediction. Nonspecific microsomal binding can present another confounding factor in the

calculation of kinetic constants for human liver microsomal drug metabolism reactions, leading to overestimation of K_m and, hence, underprediction of CL_{int} . Finally, glucuronidation reactions are usually more complicated than CYP-mediated oxidation reactions. Although the Michaelis–Menten plots are generally used to fit the kinetic data, the glucuronidation reactions have a tendency to exhibit nonlinear kinetic behavior [11,78]. Hence, unless a proper non-Michaelis–Menten model is applied, the CL prediction obtained from these data will not be predictive of the *in vivo* clearance observed in humans. Thus, the interpretation and analysis of drug glucuronidation kinetic data can further impact the reliability and predictive value of *in vitro* CL_{int} .

Miners *et al.* [76] have shown that underprediction persists even when the above confounders (nonspecific binding, scaling factors, inappropriate kinetic modeling, and failure to account for extrahepatic metabolism) are added into the equation and experimental conditions are optimized. Most often, such discrepancies have been ascribed to the high K_m values that are observed following kinetic experiments, which employ HLM or recombinant enzymes. For example, K_m values from HLM for the UGT2B7 substrates, morphine and zidovudine, range from ~ 1100 to $4300 \mu M$ following incubation with HLM or recombinant UGTs [87]. The high K_m values, in turn, result in an underestimation of *in vitro* and extrapolated *in vivo* CL_{int} . This overestimation of the K_m values has been attributed to the presence of the long chain unsaturated fatty acids, notably arachidonic, linoleic, and oleic acids, released from membranes during the course of an incubation. These fatty acids act as potent competitive inhibitors of some of the UGT enzymes, rendering the estimation of K_m to be inaccurate. The addition of bovine serum albumin (BSA) or fatty-acid-free human serum albumin (HSA-FAF), which sequester the inhibitory fatty acids, to incubations of recombinant UGT or HLM results in a 5- to 10-fold reduction in K_m values with HLM and recombinant UGT as the respective enzyme sources, thereby increasing the CL_{int} of these compounds [88,89]. This effect appears to be more pronounced with UGT1A9 and UGT2B7. For example, extrapolation of the microsomal CL_{int} for the glucuronidation of the UGT2B7 substrate, zidovudine, generated in the presence of BSA, HSA-FAF, or human intestinal fatty acid binding protein (IFABP), resulted in a threefold underprediction of CL_H [89,90], compared to an up to 23-fold underprediction for data generated without fatty-acid sequestration [87,90]. Similar results have been reported for several other drugs glucuronidated predominantly by UGT2B7, using the substrate-depletion approach [75].

In contrast to UGT1A9 and UGT2B7, fatty acids do not appear to affect the *in vitro* activities of UGT1A1, UGT1A4, and UGT1A6 [88,91]. This is illustrated by the clearance predictions of profolol. The K_m (and therefore CL_{int}) values are essentially unaltered by the presence of albumin. Thus, the CL prediction with BSA supplemented HLMs and recombinant UGT 1A9 enzyme were within range compared to the clearance values obtained from incubations that were conducted in the absence of BSA.

7.8 FACTORS AFFECTING UGT ACTIVITY AND ITS CLINICAL SIGNIFICANCE

Numerous factors such as age, diet, disease states, ethnicity, genetic polymorphisms, DDIs, and hormonal effects are known to alter human UGT activity *in vivo* [14,78,92–94]. Knowledge of these factors that are responsible for this variation is of

considerable importance, since they can affect both drug efficacy and toxicity. Only the impact of genetic polymorphisms and DDI on UGT activity *in vivo* is discussed here.

7.8.1 Genetic Polymorphism

Genetic variations and single nucleotide polymorphisms within the UGT family of enzymes is relatively common [95]. In the UGT1 family, genetic polymorphisms have been detected for UGT1A1, 1A6, 1A7, 1A8, 1A9, and 1A10, while in the UGT2 family, genetic polymorphisms of UGT2B4, 2B7, and 2B15 have been reported [96,97]. Genetic polymorphism of UGT1A1 has been extensively studied because of its role in well-known hereditary jaundices. Mutation in UGT1A1 leads to Gilbert syndrome, a mild hereditary unconjugated hyperbilirubinemia. In some cases, certain mutations in UGT1A1 can result in a severe condition called *Crigler–Najjar syndrome*, which may lead to brain damage in infants. Besides its association with hereditary disease, mutations in genes encoding UGT enzymes may also have clinical relevance to a drug's pharmacokinetics and clinical outcomes, as illustrated by the examples of irinotecan and MPA. As mentioned earlier, the active metabolite (SN38) of irinotecan is inactivated primarily by UGT1A1. One of the polymorphisms of UGT1A1, the UGT1A1*28 allele, which has 7 TA repeats in a TATA box of the promoter of *UGT1A1* gene, shows reduced expression of the enzyme with resultant decreased glucuronidation activity compared to its wild-type allele (UGT1A1*1), which has 6 TA repeats. This genetic change is associated with a condition called *Gilbert's syndrome*. Patients homozygous for UGT1A1*28 have reduced glucuronidation of SN38 and an elevated risk of adverse effects from this metabolite, including diarrhea and bone marrow suppression compared with patients with one or two wild-type alleles [98,99]. Besides UGT1A1*28, emerging data suggest that polymorphisms in UGT1A7*3/*3 genotype has also been shown to predict hematologic toxicity in the first cycle of irinotecan treatment, while UGT1A1*60 was a better predictor of SN38 glucuronidation [100]. Thus, genotyping with haplotype rather than a single polymorphism may provide better prediction of those patients who are at the highest risk of toxicity [101]. Ethnic differences may also play an important role in determining the appropriate genotype for assessment. For instance, in East Asians, the frequency of UGT1A1*28 is only one-third of that in the Caucasians or African-Americans. However, another low activity allele, UGT1A1*6, shows the same frequency as UGT1A1*28 in East Asians but is not detected in the Caucasians and African-Americans. A pharmacokinetics/pharmacodynamics study in Japanese cancer patients showed that the haplotypes significantly associated with reduced area under the concentration curve ratio (SN38 glucuronide to SN38) and neutropenia contained UGT1A1*6 or UGT1A1*28 [102]. A retrospective analysis in Japanese cancer patients revealed a significant association of neutropenia with UGT1A1*6 [103], illustrating the importance of taking ethnic differences in pharmacogenetic traits into consideration.

Another example of the potential impact of UGT polymorphisms on drug metabolism and interindividual variation in pharmacokinetics is demonstrated using mycophenolate mofetil (MMF). MPA, an active metabolite of MMF, is a selective inhibitor of inosine monophosphate dehydrogenase. The pharmacokinetics of this drug shows substantial interindividual variability in humans [104,105]. Because MPA has a narrow therapeutic index, variations in its concentrations can result in acute toxicity or transplant rejection. Following administration to humans, MMF, which is a prodrug,

is converted to its active metabolite MPA, which then undergoes further metabolism by glucuronidation of the phenolic hydroxyl group (major metabolite) and, to a lesser extent, formation of an acyl glucuronide. The glucuronide conjugates are subsequently excreted in urine [106,107]. *In vitro* studies indicate that glucuronidation of MPA to its hydroxyphenyl glucuronide conjugate is mediated mainly by UGT1A9 in the liver and by UGT1A7, 1A8, and 1A10 extrahepatically [108,109]. The formation of the acyl glucuronide is mediated by UGT2B7 [109].

Since UGT1A9 plays a major role in the glucuronidation of MPA, several studies have been conducted to evaluate the impact of genetic polymorphisms of this enzyme on MPA pharmacokinetics. Results suggest that in healthy volunteers and in renal transplant patients, carriers of the UGT1A9 promoter single nucleotide polymorphism (SNPs) –2152 C>T and –275 T>A were associated with lower systemic exposure to MPA [110,111] and predicted the risk of developing acute rejection in renal transplant patients [111]. The less frequent UGT1A9*3 SNP was associated with a higher MPA systemic exposure. In addition to these SNPs, Baldelli *et al.* [112] have also shown that –440 C>T and –331 T>C SNPs of the UGT1A9 promoter region were associated with an increased systemic exposure to MPA in renal transplant patients. Besides UGT1A9, the role of genetic polymorphisms in other UGTs on MPA pharmacokinetics is less clear. For example, UGT1A8*2/*2 has been associated with a slight increase in MPA AUC (18%) only in patients receiving concomitant cyclosporine (CsA), but not in patients receiving concomitant tacrolimus [111]. However, Johnson *et al.* [113] have reported that MPA dose-adjusted trough concentration was 60% higher in subjects heterozygous or homozygous for UGT1A8*2 than in those with wild type; this effect is apparent only in patients receiving concomitant tacrolimus. The reason for this discrepancy is unknown.

Recent investigations evaluating the potential contribution of UGT polymorphisms to adverse events of MPA revealed that polymorphism in the UGT2B7 promoter region –840G>A was found not to be associated with the incidence of leucopenia or diarrhea [114]. However, in a pilot study in pediatric kidney transplant recipients, Prausa *et al.* [115] showed that carriers of the polymorphisms in the UGT1A9 -331 and, possibly, of UGT2B7 -900 SNPs appeared to be associated with an increased risk for developing an adverse event such as leucopenia. If confirmed, dosing recommendations for MMF may need to be reevaluated based on the genotype to ensure safe use of this drug while maintaining its therapeutic benefits [115].

7.8.2 Drug–Drug Interactions

Management of many diseases requires the use of multiple drug therapy, which predisposes the patients to an increased risk of experiencing DDIs through alteration of the clearance mechanisms by the interacting drugs. The most common mechanisms involved in UGT-mediated DDIs include inhibition or induction of the UGT enzymes. Other proposed mechanisms may involve alterations of availability of UDPGA and/or inhibition of the excretion of glucuronides, with subsequent hydrolysis of the glucuronides to parent substrate aglycone [116]. Several classes of drugs have shown to inhibit UGTs [12]. Moreover, no specific inhibitors of individual UGT isoforms have been identified that may be safely administered clinically. Although not completely selective, more recently erlotinib, a reversible inhibitor of the epidermal growth factor

receptor, exhibited selective potent competitive inhibition against 4-MU and bilirubin glucuronidation by UGT1A1 [117]. Similarly, atazanavir is shown to be a potent inhibitor of UGT1A1 [118], while fluconazole inhibits UGT2B7 [119]. As the CYPs, several enzymes in UGT family are subject to induction on the basis of *in vitro* experiments conducted with primary cultures of human hepatocytes or cultured human cell lines. Inducible human UGT enzymes include UGT1A1 [120,121], UGT1A3, UGT1A4 [122], UGT1A6 [122–124], UGT1A9 [124], and UGT2B7 [122,124]. Many common inducers of CYP enzymes such as oral contraceptives, rifampin, phenobarbital, phenytoin, and carbamazepine can increase the expression of UGTs [125].

Since clinical studies on DDIs involving inhibition or induction of UGT enzymes have been extensively reviewed [12,116,126], this section focuses on the DDI with drugs that are of narrow therapeutic index with potentially important clinical implications resulting from DDI such as zidovudine, MPA, and lamotrigine.

7.8.3 Inhibition of Glucuronidation

7.8.3.1 Zidovudine. Among the drugs that undergo glucuronidation as a major clearance mechanism, zidovudine has been one of the most extensively evaluated drugs for UGT-mediated DDI [12,127]. In humans, zidovudine is renally eliminated primarily as a glucuronide conjugate of the parent drug [128]. *In vitro*, glucuronidation of zidovudine is predominantly mediated by UGT2B7 [87,129–131]. Several DDIs involving zidovudine and other agents such as atovaquone, fluconazole, and probenecid have been reported [132–134]. For instance, coadministration of atovaquone 750 mg Q12h and zidovudine 200 mg Q8h for 12 days was associated with a 33% increase in zidovudine AUC compared to zidovudine alone [132]. A concomitant decrease in zidovudine glucuronide levels was observed, suggesting that the mechanism of interaction may be related to inhibition of zidovudine glucuronidation. Similarly, patients who received concomitant administration of fluconazole (400 mg daily) and zidovudine (200 mg Q8h) for 7 days exhibited an increase in the AUC and $C_{\max}$ of zidovudine by 74% and 84%, respectively [133]. The apparent oral formation clearance to zidovudine glucuronide decreased by 48%, which suggests that a likely mechanism of this interaction is attributable to inhibition of glucuronidation. Likewise, concurrent administration of probenecid to patients with AIDS resulted in a twofold increase in the mean plasma AUC of zidovudine and its glucuronide conjugate compared to administration of zidovudine alone [134]. Probenecid administration also significantly reduced the renal clearance of zidovudine glucuronide as well as the zidovudine glucuronide to zidovudine urinary excretion ratio. A mechanism of this interaction may involve, at least in part, inhibition of glucuronidation by probenecid. However, this was confounded by the observation that the plasma concentration of probenecid achieved (200–400 μM) was considerably lower than the *in vitro* K_i value for probenecid to inhibit zidovudine glucuronidation in HLMs (700–900 μM). A proposed alternative explanation for the increase in plasma AUC of zidovudine involves probenecid inhibiting the renal tubular secretion of zidovudine glucuronide, with subsequent hydrolysis of the glucuronide conjugate back to the parent drug [116]. Further evidence is needed to support this alternate hypothesis. Other DDI studies of zidovudine with drugs such as efavirenz (Sustiva prescribing label), methadone, and valproic acid have also been reported [135–137]. These studies showed changes in zidovudine systemic exposure ranging from no increase (efavirenz) to a twofold (valproic acid) increase.

7.8.3.2 Mycophenolate Motevil (MMF). Assessment of MPA pharmacokinetics in renal transplant patients indicates that patients receiving tacrolimus and MMF displayed a 56% increase in AUC of MPA compared to those who received MMF and CsA [138]. Conversely, the AUC of MPA glucuronide was ~40% lower in these patients. A subsequent *in vitro* study demonstrates that tacrolimus inhibits the conversion of MPA to its hydroxyphenyl glucuronide in a concentration dependent manner, providing evidence to support that the interaction between tacrolimus and MPA may be mediated by inhibition of UGT [139].

7.8.3.3 Lamotrigine. Lamotrigine is an antiepileptic drug indicated for the treatment of partial seizures, primary generalized tonic-clonic seizures, and bipolar disorder. In humans, lamotrigine is primarily metabolized to form a 2*N*-glucuronide conjugate, which was excreted in urine [140]. *In vitro*, glucuronidation of lamotrigine is mediated by UGT1A3 and UGT1A4, and possibly UGT2B7 [91,141]. Several DDI studies with lamotrigine have been reported, which likely involve inhibition or induction of the UGT(s) mediating the glucuronidation of this drug. A study conducted in six healthy male subjects revealed that concomitant administration of valproic acid (200 mg Q8h for two days) increased the plasma lamotrigine AUC by ~30% and prolonged its elimination $t_{1/2}$ from 37 to 48 h [142]. Renal clearance of lamotrigine remained unchanged. The authors postulated that the explanation for this observation likely was related to valproic acid impairing lamotrigine glucuronide formation in the liver, although assessment of the pharmacokinetics for this metabolite was not performed in this study.

7.8.3.4 Induction of Glucuronidation.

7.8.3.4.1 Zidovudine. *In vitro*, rifampin is a known inducer of selected isoforms of UGT enzymes [125,143]. In humans, rifampin coadministration decreased plasma zidovudine C_{max} and AUC by 43% and 47%, respectively, and urinary recovery of zidovudine by 37% [144]. In contrast, rifampin minimally altered the plasma C_{max} and AUC of zidovudine glucuronide, while urinary recovery of this metabolite increased by 11%. Ratio of plasma AUC of zidovudine glucuronide to zidovudine increased 99% by rifampin, while the urinary ratio of metabolite to parent increased by 75%. Since rifampin increased the oral formation clearance of its glucuronide metabolite by twofold while renal clearance of zidovudine and its glucuronide conjugate was unchanged, this supports the hypothesis that the mechanism of this interaction likely results from the induction of the relevant UGT enzyme(s) by rifampin. Similarly, coadministration of ritonavir along with zidovudine has also been shown to affect the systemic exposure of zidovudine in human [145]. Ritonavir administration reduced plasma zidovudine C_{max} and AUC by about 26% while there was little change in the systemic exposure to zidovudine glucuronide. Since the urinary recovery of parent and metabolite was not reported, it could not be confirmed if the apparent change was related to induction of UGT enzymes.

7.8.3.4.2 Lamotrigine. A few case reports indicate that concomitant use of oral contraceptives and lamotrigine increased seizure frequency or recurrence of seizures, which could be attributed to altered levels of lamotrigine in these women [146]. A subsequent study showed that in the presence of the oral contraceptives, steady-state lamotrigine C_{max} and AUC values decreased by 39% and 52%, respectively [147]. This magnitude of change likely is clinically relevant with direct implication of dosing

of lamotrigine in women who may initiate or stop a combined oral contraceptive with this drug. Similarly, administration of multiple doses of a combination of atazanavir (300 mg) and ritonavir (100 mg) has also been shown to affect the pharmacokinetics of lamotrigine in healthy male volunteers, although atazanavir alone did not appear to have a significant effect [148]. Lamotrigine plasma AUC and elimination half-life decreased by 32% and 27%, respectively. Likewise, a combination of lopinavir and ritonavir reduced the plasma AUC and elimination half-life of lamotrigine by ~50% [149]. The median ratios of AUC for the 2*N*-glucuronide conjugate to parent increased from 0.57 to 1.12, suggesting that the likely mechanism of this interaction may be related to an induction of UGT enzyme(s) responsible for the glucuronidation of lamotrigine.

7.8.3.4.3 Mycophenolate Mofetil. In eight stable renal allograft recipients, all treated with MMF without concomitant use of calcineurin inhibitors, administration of rifampin for eight days led to a decrease in plasma exposure of MPA with most reduction occurring at 6–12 h postdose [107]. This suggested that rifampin alters the enterohepatic recirculation of MPA. Rifampin also increased plasma AUC for MPA glucuronide and mycophenolic acyl glucuronide by 34% and 193%, respectively. Urinary recovery of these two glucuronide conjugates also increased by 49% and 138%, respectively, but renal clearance did not change with rifampin treatment. An increase in oral formation clearance of these glucuronide conjugates is consistent with the hypothesis that rifampin induces MPA glucuronidation. In addition, rifampin may also alter the excretion/transport of MPA glucuronide conjugates, thus impacting the systemic exposure and enterohepatic recirculation of this drug.

Telmisartan, an angiotensin receptor blocker, has been shown to reduce the exposure of MPA in Japanese renal transplant recipients having urine protein or hypertension [150]. Telmisartan coadministration was associated with a 29% decrease in mean dose-adjusted plasma AUC of MPA in patients receiving combination immunosuppressive therapy of tacrolimus, MMF, and corticosteroids. Conversely, coadministration of valsartan or candesartan did not alter the pharmacokinetics of MPA. This disconnect was attributed to the fact that telmisartan, but not valsartan or candesartan, is a peroxisome proliferator-activator receptor gamma (PPAR- γ) activator, which enhances UGT1A9 expression *in vitro* [151]. Thus, telmisartan may stimulate the metabolism of MPA to its glucuronide conjugate and decreased the systemic exposure to MPA. Interestingly, telmisartan coadministration did not alter the plasma pharmacokinetics of MPA glucuronide compared to the other three groups. Thus, further work will be needed to confirm the mechanism of this interaction.

7.9 CLINICAL IMPLICATIONS OF UGT-BASED DRUG-DRUG INTERACTIONS

The examples presented in this chapter as well as those from other reviews illustrate that with a few exceptions, DDI involving inhibition of UGT typically results in a modest (twofold or less) increase in the systemic exposure of the substrate. This contrasts sharply with those observed with CYP DDI, which could result in upward of 20- to 30-fold increase in AUC of the victim drug. Williams *et al.* [126] and Lin and Wong [116] have postulated several reasons for this observation: low substrate affinity to the UGT enzymes (or high K_m values), low inhibitor affinity to the UGT enzymes relative to the inhibitor concentration (or relatively low I/K_i ratio), and presence of multiple

enzymes (both CYPs and UGTs) that mediate the metabolism of the substrates. To date, evidence of increased toxicity arising from DDI involving UGT inhibition is rare. Nevertheless, for any given drug, the clinical consequence of such an interaction should be considered in light of its exposure-toxicity relationship. Likewise, induction of UGT enzymes was associated with a reduction of the AUC for the affected drug by ~50%, which is considerably less than those observed with CYP induction. However, despite this relatively modest change, clinical consequences may still arise as exemplified by the increased seizure frequency from the lamotrigine–oral contraceptive combination. Thus, patients should be monitored closely while dose adjustment should be considered for those drugs that display a narrow therapeutic index.

7.10 SUMMARY

This chapter has provided an overview of the role and clinical consequences of glucuronidation of drugs by UGTs. Glucuronidation via UGT enzymes not only contributes to multiple important physiologic functions in the body involving regulation of the homeostasis of endogenous substances, but is an important detoxification pathway and a major clearance mechanism for certain drugs. Because of their ubiquitous nature, UGTs can affect the pharmacokinetics and the disposition of drugs. Intestinal UGTs can contribute to the presystemic “first-pass” metabolism and therefore the drug’s bioavailability. This can indirectly influence the biological responses to drugs. In addition to detoxification, glucuronidation of certain drugs can lead to bioactivation and therefore induce drug toxicity. As the CYPs, genetic polymorphisms have been observed in the UGT family. These abnormalities have been associated with diseases such as hyperbilirubinemia and/or an increased risk of certain cancers. Genetic polymorphisms of this diverse super family of enzymes also contribute to wide interindividual variation in pharmacokinetics of drugs that are metabolized by these enzymes, which may predispose patients to an increased risk of untoward effects. For drugs with narrow therapeutic index and severe toxicity (e.g., irinotecan), genetic testing to guide dose selection may be warranted. In general, the magnitude of DDI as a result of modulation of UGT enzyme expression or activity is considerably less than those observed with CYP enzymes. However, appropriate monitoring of the potential clinical outcome of such changes is still prudent. At this time, prediction of *in vivo* clearance from *in vitro* systems appears to be feasible for selected drugs/UGT enzyme pairs; however, this remains an area of scientific uncertainty.

8.1 SUMMARY

Medication with plants and herbs has been practised for thousands of years, and a substantial proportion of the world's population is thought to use herbal medicines. As a result of their widespread use, herbal medicines are likely to be taken with prescribed drugs, leading to the risk of herb–drug interactions. Herbal consumption can diminish the therapeutic effect of drugs as well as giving rise to adverse reactions and toxicity. These clinical effects are caused by herb–induced changes in (i) pharmacokinetics, particularly through inhibition or induction of the cytochrome P450 drug-metabolizing enzymes (CYPs) and (ii) drug receptor sensitivity. St. John's wort has been the subject of much research on herb–drug interactions. It induces the activity of human cytochrome P450s, particularly, CYP3A4, which has led to the characterization of interactions involving more than 100 drugs. Decreased or loss of therapeutic effect has been observed for drugs such as immunosuppressants, oral contraceptives, and methadone. Other herbs that have been shown to cause pharmacokinetic interactions, the significance of which requires confirmation in many cases, include Echinacea, garlic, ginkgo, ginseng, kava, and milk thistle.

Because of the regularity in food intake, therapeutic drugs may be taken before, at the same time as, or after a meal. There are many instances whereby food itself as well as its constituents has been shown to influence the pharmacokinetics of drugs and response to drugs, sometimes causing substantially diminished therapeutic effects or adverse reactions. The most notable and widely studied example of a food product interacting with drugs is that of grapefruit juice. The juice is an inhibitor of CYP3A4,

and has been shown to impair the metabolism of a large number of drug substrates of this enzyme, in some cases leading to clinically significant interactions.

It should be said that much of the published evidence on herb-drug and food-drug interactions is based on case reports or on pharmacokinetic data alone, and these require substantiation by studies measuring the clinical effects of drugs. Because herbal and food products are not regulated to the same extent as therapeutic drugs, and because of the variability in the clinical effects produced, herb and food interactions are more difficult to document, characterize, and predict. Caution should be exercised in the use of pharmaceutical drugs with herbal remedies and food.

8.2 INTRODUCTION

Humans have used plants and herbs as medicines for thousands of years. It has been estimated that at least 20% of the general population in the United States use herbal medicines [1,2], and that about 20–26% of people in the United Kingdom had bought over-the-counter herbal medicines over the last one to two years [3]. Because they occur naturally, many users take the view that herbal medicines are harmless, and many do not reveal their use to their health-care provider. However, it is established that some herbal medicines, which are often a mixture of active ingredients, can cause adverse effects [4]. As a result of their widespread use, herbal medicines are likely to be taken with therapeutic drugs leading to the risk of herb-drug interactions, occurring both from changes in pharmacokinetics and at the level of the receptor, that is, pharmacodynamics.

Because of the regularity in food intake, therapeutic drugs may be taken before, at the same time as, or soon after a meal. There is a large literature on how food itself as well as its constituents can influence the pharmacokinetics of and pharmacodynamic response to drugs, sometimes causing substantially diminished therapeutic effects or adverse reactions [5].

The aim of this chapter is to review the relevant literature on herb-drug and food/food constituent-drug interactions and their clinical importance. The greatest coverage is devoted to drug interactions involving St. John's wort and grapefruit juice, because they have been the subject of most research. The chapter begins with a description of the mechanisms by which drug interactions occur.

8.3 DRUG INTERACTIONS

When two or more drugs are administered to a patient at the same time, there are several possible consequences. First, one drug could enhance the therapeutic effect of another, and there are a number of examples of these beneficial drug-drug interactions. Second, one drug could diminish or abolish the therapeutic effect of another, an unwanted effect. Third, two drugs might interact to cause an adverse drug reaction or toxicity.

The question of how common drug-drug interactions are, is difficult to answer. The results of a relatively recent and large prospective study suggested that drug-drug interactions were responsible for about 1% of admissions to two UK hospitals over a period of six months [6]. There is also good evidence that the more the number of drugs taken by a patient, the greater the risk of an interaction [7].

Drug–drug interactions occur through a variety of mechanisms: (i) pharmaceutical incompatibility, where there is a chemical reaction between two drugs (in some cases, leading to precipitation from solution), precluding their use in the same formulation; (ii) pharmacodynamics, where the action of one drug is altered by another at the site of pharmacological action, that is, the receptor or by a physiological mechanism; (iii) pharmacokinetics, where the absorption, distribution, metabolism, or excretion of one drug is affected by the coadministration of another [5]. In recent years, many important drug–drug interactions have been identified that involve inhibition or induction of the drug-metabolizing enzymes, notably the cytochrome P450s (CYPs). Drug–drug interactions mediated by CYPs will form a substantial part of this chapter.

8.4 DRUG–HERB INTERACTIONS

This chapter is restricted to a discussion of herb–drug interactions involving commonly used drugs and to those interactions where there is at least some evidence of a clinically significant effect. For more detailed and comprehensive coverage of drug–herb interactions, the reader is referred to reviews by Izzo and Ernst [1], Hu *et al.* [8], Shord *et al.* [2], Williamson *et al.* [9], Kennedy and Seely [10].

8.4.1 St. John's Wort

St. John's wort or *Hypericum perforatum* is a plant with yellow flowers. It appears to be named after John, the Baptist, since it flowers in late June at the time of the feast of St. John [11]. Its most common use is for the treatment of depression [12]. The major active components of St. John's wort are hypericin and hyperforin, although it contains many other chemicals [8]. The inhibition of 5-hydroxytryptamine, dopamine, and noradrenalin by St. John's wort [13] may form the basis of its antidepressant effect. Izzo [14] cites a number of cases of the serotonin syndrome (characterized by increased heart rate, shivering, sweating, agitation, or more seriously hyperthermia, high blood pressure, coma, and/or rhabdomyolysis) occurring when St. John's wort is taken with serotonin–reuptake inhibitors. However, existing evidence suggests that St. John's wort has relatively few unwanted effects [15].

Many *in vivo* studies have shown that a range of interactions, mainly pharmacokinetic and some clinically important, occur through the coadministration of St. John's wort with prescribed drugs. The major mechanism for these interactions is the induction of CYP activity as well as P-glycoprotein (PgP) by St. John's wort, leading to decreased and sometimes subtherapeutic plasma drug concentrations. The most important group of interactions involving St. John's wort, with respect to both number and clinical significance, occur through the induction of CYP3A4 [2]. St. John's wort can also induce CYP2C19 [16] and CYP2E1 [17], enzymes that are generally less important than CYP3A4 in human drug metabolism. Three other significant drug-metabolizing CYPs, CYP1A2, CYP2C9, and CYP2D6, do not appear to be induced by St. John's wort [18].

Shord *et al.* [2] review the ability of St. John's wort to inhibit rather than induce the activity of a range of human CYPs *in vitro*, but the relationship between the inhibition and induction of CYP by St. John's wort *in vivo* is unclear.

There is evidence that St. John's wort can induce the transport protein PgP [19,20]. The considerable overlap among substrates, inducers, and inhibitors of PgP and CYP3A4 indicates that both proteins may contribute to the many interactions originally attributed to CYP3A4 alone.

8.4.1.1 Immunosuppressive Drugs. There are numerous case reports of interactions between St. John's wort and drugs used to prevent rejection of transplanted organs [21], two of which, cyclosporin and tacrolimus are well-established substrates of CYP3A4 and PgP. Coadministration of St. John's wort resulted in decreased plasma concentrations of the immunosuppressives in some cases to subtherapeutic values, leading to instances of organ rejection. Organ function improved in the majority of patients on withdrawal of St. John's wort. In one substantial report, 30 transplant patients taking St. John's wort experienced a 47% average decrease in plasma cyclosporin concentrations [22]. Titrating the dose of cyclosporin upward brought the plasma concentrations back to the preinteraction levels. When St. John's wort was stopped, the patients were stabilized on the same dose of cyclosporin that they were taking before the interaction.

Another case report involved a renal transplant patient receiving tacrolimus and mycophenolate to prevent rejection [23] (Fig. 8.1). Following self-medication with St. John's wort, tacrolimus concentrations decreased by about fourfold, which was

Figure 8.1 Tacrolimus whole blood trough concentrations, serum creatinine, and daily tacrolimus dosage in relation to St. John's wort intake in a renal transplant patient. *Source:* From Bolley *et al.*, 2002; with permission.

accompanied by a decreasing renal function. Withdrawal of St. John's wort led to the return of tacrolimus concentrations to the preinteraction range, and to an improvement in renal function.

The effect of St. John's wort on the pharmacokinetics of cyclosporin and tacrolimus has been corroborated in several prospective clinical trials [1]. In one study of renal transplant patients receiving 600 mg of St. John's wort extract for 14 days, trough plasma cyclosporin concentrations decreased by a mean of 41%, requiring a near doubling of the dose of the latter to maintain an adequate degree of immunosuppression [24].

Bell *et al.* [25] showed that concurrent administration of St. John's wort had no significant effect on the single-dose pharmacokinetics of prednisone and prednisolone in healthy males.

8.4.1.2 Oral Contraceptives. There is substantial *in vivo* evidence that St. John's wort enhances the elimination of the active constituents of the contraceptive pill. Hormonal components such as ethinylestradiol [26], 3-ketodesogestrel [27], and norethindrone [28] are all metabolized by CYP3A4, and St. John's wort has been demonstrated to hasten their clearance [1]. In this context, a number of reports of unwanted pregnancies in women taking oral contraceptives and St. John's wort have been reported to the European drug regulatory authorities [29]. In a more detailed report, Schwarz *et al.* [30] describe a 36-year-old depressed woman attending a gynaecology clinic with an unexpected pregnancy. She was a regular user of an oral contraceptive containing ethinylestradiol and dienogestrol, and then began taking over-the-counter hypericum extract three months before conception. Use of the oral contraceptive was terminated, resulting in a healthy foetus. Breakthrough bleeding has also been reported in women taking oral contraceptives and St. John's wort [1]. For example, in a randomized controlled trial of 18 healthy females taking oral contraceptives [31], the authors found that St. John's wort (300 mg twice or three times daily) was associated with an increase in intracyclic bleeding episodes, but that there was no evidence of ovulation. Furthermore, St. John's wort was associated with a decrease in the plasma concentration of 3-ketodesogestrel but not that of ethinylestradiol. The induction of the metabolism of the active constituents of the contraceptive pill by St. John's wort leading to subtherapeutic concentrations probably caused these pregnancies and episodes of breakthrough bleeding. Because of the risk of a loss of therapeutic effect, the Committee on the Safety of Medicines UK [32] has advised that St. John's wort should not be used with oral contraceptives.

8.4.1.3 Anticancer Drugs. Yang *et al.* [33] have reviewed herbal interactions with anticancer drugs, and some may be clinically significant. For example, St. John's wort decreased the plasma concentrations of the active metabolite of irinotecan by 42%, which was accompanied by reduced myelosuppression [34]. Similar effects on the clearance of imatinib during treatment with St. John's wort have been observed [35]. Both of these drugs are metabolized by CYP3A4. Avoidance of St. John's wort should reduce the risk of subtherapeutic concentrations of these drugs.

8.4.1.4 Anti-HIV Drugs. Although St. John's wort has been shown to decrease the concentrations of the antiretroviral drugs, indinavir [36] and nevirapine [37], the clinical significance of this reaction remains to be established. Both Izzo and Ernst

[1] and Hu *et al.* [8] cite a case of an increased HIV RNA viral load in a patient being treated with indinavir and lamivudine, and who was also taking St. John's wort. Although this appears to be the only report of diminished therapeutic effect of anti-HIV treatment in patients taking St. John's wort, The European Medicine Evaluation Agency [38] has advised against the use of protease inhibitors with St. John's wort.

8.4.1.5 Drugs Affecting the CNS. St. John's wort has been shown to interact with antidepressant drugs, such as paroxetine and sertraline, that block serotonin reuptake in the brain, leading to the "serotonin syndrome" [39]. Symptoms can include increased heart rate, shivering, sweating, agitation, or more seriously hyperthermia, high blood pressure, coma, and rhabdomyolysis. A complex case of a patient exhibiting mania when taking St. John's wort and sertraline is described by Barbenel *et al.* [40]. This patient was advised to stop taking St. John's wort before starting sertraline but declined. His symptoms included overarousal, distractibility, and delusions of grandeur. Use of St. John's wort taken alone has also been associated with the serotonin syndrome [41]. Because the clinical significance of this interaction is not fully understood, Hu *et al.* [8] advise that the combined use of St. John's wort and the selective serotonin reuptake inhibitor (SSRI) antidepressants should be avoided.

Chronically administered St. John's wort has been shown to decrease the concentrations of several benzodiazepines [1], notably midazolam, which is an important substrate of CYP3A4 [42]. Wang *et al.* [18] have performed one of the most comprehensive studies on the effect of St. John's wort on the pharmacokinetics of midazolam. Administration of St. John's wort to healthy subjects for two weeks (900 mg/day) caused a >50% decrease in the plasma concentration of midazolam, but the effect on the pharmacodynamics was not assessed. Decreased efficacy of the benzodiazepines when they are given with St. John's wort over the long term should be anticipated, although more research is needed to define the effects of the herb on the sedative properties of these drugs.

Interactions between St. John's wort and treatments for opiate dependence have been identified. Eic-Hochli *et al.* [43] reported that St. John's wort (900 mg/day for 14–47 days) was associated with a 19–60% decrease in methadone plasma concentration-to-dose ratios in four patients taking methadone. Two of these patients reported symptoms of withdrawal. Single cases of mania [44] and orofacial dystonia [45] have been described in patients taking bupropion, a drug used to aid smoking cessation. In a recent study in Chinese healthy males, St. John's wort (975 mg/day for two weeks) decreased the AUC of bupropion by 14% [46].

8.4.1.6 Cardiovascular Drugs. The Swedish Medical Products Agency have described seven case reports between 1998 and 1999 of patients who were stabilized on the anticoagulant, warfarin [47]. (Table 8.1). On taking St. John's wort, their international normalized ratio (INR) decreased from the normal range 2–4 to about 1.5. A dosage increase was required in two patients. When St. John's wort was withdrawn, the INR values returned to the normal range in four of the patients. The likely mechanism for this interaction is the induction of the activities of CYP2C9, although other studies have shown that CYP2C9 is not inducible by St. John's wort [18], and CYP3A4 both of which catalyze the metabolism of warfarin. In a randomized crossover study in healthy subjects, administration of St. John's wort for 14 days led to a relatively small decrease in the AUC of both *R*- and *S*-warfarin [48].

TABLE 8.1 Seven Cases of Decreased Effect of Warfarin During Concomitant Treatment with St. John's Wort

Patients	INR Before	INR During	Duration of Warfarin Treatment	Warfarin Dose once St. John's Wort Treatment Started
79 years, female	2.5–3.8	1.7	2.5 years	Increased from 18.5 to 21.25 mg/week
65 years, male	2.4–3.6	2.0–2.1	4 years	Increased from 37.5 to 40 mg/week. INR returned to 2.7 on the ordinary dose of 37.5 mg/week once St. John's wort was stopped
76 years, male	2.3	1.1	10 days	Increased
61 years, female	NA	1.2	Years	INR decreased and then increased after St. John's wort was stopped
84 years, female	2.9–3.6	1.5	Stable ≥ 6 mo	Stable for ≥ 6 mo. INR returned to target range once St. John's wort stopped
56 years, female	2.6	1.5	Unknown	INR returned to previous value after St. John's wort stopped
85 years, male	2.1–4.1	1.5	Long time	INR decreased so dose increased while St. John's wort was continued

Abbreviation: NA, not available.

Source: From Yu *et al.*, 2000; with permission.

St. John's wort (900 mg/day for 14 days) given to eight healthy subjects who had been administered racemic verapamil jejunally, decreased the AUC of its R- and S-isomers by 78% and 80%, respectively [49]. Similarly, St. John's wort caused a 40% decrease in the AUC of nifedipine, administered to healthy subjects given a 10-mg oral dose of the drug [50]. The pharmacodynamic consequences of the effect of St. John's wort were not assessed in either of these studies.

St. John's wort (900 mg/day for two weeks) decreased the AUC of simvastatin (10 mg), a widely used cholesterol lowering drug, by 62% but had no effect on the pharmacokinetics of pravastatin (20 mg) in healthy subjects [51]. The clinical significance of this decrease was not established. St. John's wort (600 mg/day for four weeks) caused a small (12%) but significant increase in serum concentrations of low density lipoprotein (LDL) in 16 patients with hypercholesterolemia treated with a stable dose of atorvastatin (10–40 mg/day) for at least three months [52]. The authors suggest that there may be a need to increase the dose of atorvastatin in patients taking St. John's wort. Simvastatin and atorvastatin but not pravastatin are substrates of CYP3A4 and PgP [51].

Digoxin, which is used to treat heart failure, is a substrate of PgP [53], which is induced by St. John's wort [20]. The herb (900 mg for 10 days) decreased the AUC and trough concentration of digoxin given to healthy subjects for five days, by 28% and 37%, respectively [54]. In a further study in healthy subjects, St. John's wort caused similar changes in the pharmacokinetics of digoxin [55]. Lower dose preparations of St. John's wort do not appear to affect the pharmacokinetics of digoxin [56]. Because

of the risk of toxicity the UK drug regulator has recommended that patients taking digoxin should not self-medicate with St. John's wort [32].

8.4.1.7 Other Drugs. The oral clearance of fexofenadine, a nonsedating antihistamine drug and a well-established substrate of PgP, is decreased by 12–14 days treatment with St. John's wort [57,58]. This interaction is unlikely to be of clinical significance, but it should be suspected if any loss of antihistamine effect is observed.

A case report documents an increased dose requirement for the asthma drug theophylline, a CYP1A2 substrate, in a patient who had started taking St. John's wort (300 mg/day) two months previously [59]. On stopping the herb, the serum theophylline concentrations doubled within one week, and the dose was reduced accordingly. Interpretation of this suspected interaction is confounded by the patient taking a range of other drugs and her being a smoker, in whom CYP1A2 is induced. A subsequent study in healthy subjects found that St. John's wort (900 mg/day for 15 days) did not influence the pharmacokinetics of theophylline [60].

St. John's wort (900 mg for 14 days) decreased the AUC of the proton pump inhibitor omeprazole (20 mg, single dose) by about 40%, probably by inducing CYP2C19 and CYP3A4 [61]. A dose increase in omeprazole or any of the other proton pump inhibitors, that are metabolised by CYP2C19 and CYP3A4, should be considered where there is loss of effect in patients taking this combination.

8.4.2 Echinacea

Echinacea extracts are made from the purple coneflower species of plants, which are reported to have anti-inflammatory, antiviral, anticancer, and immunostimulating effects, and are widely used for the prevention and treatment of upper respiratory tract infections [62].

There is conflicting evidence that Echinacea preparations influence the activities of the CYPs [1,63–65]. Izzo and Ernst [1] comment that these variant findings could be due to products containing different species or parts of the plant, as well as to different dosages and duration of treatment.

Gorski *et al.* [63] found that the AUC of single-dose caffeine (200 mg), a CYP1A2 substrate, was increased by about 30% in healthy subjects given *Echinacea purpurea* root (1600 mg for eight days). However, a second, similarly designed study did not confirm these findings [64]. The oral bioavailability of midazolam, a CYP3A4 substrate, given orally and intravenously to healthy subjects who had ingested *E. purpurea* root (1600 mg for 28 days) was shown to increase by 50% [63]. The pharmacodynamic consequences of this interaction were not assessed. A second study did not show any effect of Echinacea on the pharmacokinetics of oral midazolam [64]. Echinacea was found to cause a small decrease in the plasma concentrations of (*S*)-warfarin in healthy subjects, but did not affect the pharmacodynamics of this anticoagulant [66].

8.4.3 Garlic (*Allium sativum*)

Garlic is a herb belonging to the onion family. In addition to its culinary use, it is reputed to have beneficial effects on the immune and cardiovascular systems as well as antibacterial, antifungal, and antiviral properties [67]. Garlic extracts have been

shown to inhibit the activities of CYP3A4, CYP3A5, CYP2C9, and CYP2C19 *in vitro* [68] but only CYP2E1 activity appears to be inhibited *in vivo* [69,70].

There is some evidence that garlic interacts with HIV-protease inhibitors. Garlic taken in the form of a dietary supplement was associated with a 50% decrease in the plasma concentrations of saquinavir, suggesting induction of metabolism [71]. However, the results of another study with garlic extract did not support this finding [72]. Severe gastrointestinal toxicity has been reported in two patients taking concomitant garlic and ritonavir, but when these subjects were rechallenged with low dose ritonavir after they had stopped taking garlic, the symptoms reappeared [73]. No changes in the pharmacokinetics of single-dose ritonavir were observed when healthy subjects were administered garlic extract twice daily for four days [74].

Garlic has been linked to decreased platelet aggregation, but probably does not cause an important interaction with warfarin and other coumarin anticoagulants. Ingestion of garlic extract for eight weeks was associated with more than a twofold increase in the INR of a patient stabilised on warfarin [75]. When the patient stopped taking garlic, the INR decreased to its previous value. However, subsequent trials have not confirmed such an interaction, showing no effect of garlic on the pharmacokinetics and pharmacodynamics of warfarin [76,77].

McCoubrie [78] reports a patient developing low blood pressure and becoming faint when taking lisinopril and after self-administering garlic capsules. Blood pressure returned to its previous value when the garlic was stopped. No subsequent studies have been performed to explore this putative interaction.

8.4.4 Ginkgo (*Ginkgo biloba*)

The leaves of the *Ginkgo biloba* tree are used to treat circulatory disorders, such as intermittent claudication and dementia, and to enhance memory. A recent review has assessed the clinical relevance of interactions between ginkgo and drugs [79]. Izzo and Ernst [1] report some inconsistency in the results of studies investigating the effects of ginkgo on the activities of individual forms of CYP, and it appears that in most cases any effects are unlikely to be clinically significant. The influence of ginkgo on the actions of a number of drugs has been investigated.

Ginkgo has been linked to bleeding and platelet disorders [80], and thus patients taking this drug in combination with anticoagulant and antiplatelet drugs may at particular risk of bleeding. A case of intracerebral hemorrhage has been reported in a patient stabilized on warfarin for five years occurring about two months after starting ginkgo [81]. However, three reports showed that ginkgo had no effect on the pharmacokinetics, anticoagulant action, or dosage requirement of warfarin [82–84]. Meisel *et al.* [85] describe a fatal case of intracerebral bleeding in a patient taking ginkgo occurring four weeks after starting ibuprofen (600 mg/day). In another case, a subdural haematoma after a head injury was reported in a patient taking ginkgo and rofecoxib [86]. Finally, spontaneous bleeding from the iris into the anterior chamber of the eye one week after starting ginkgo was described in a patient who had been taking aspirin daily for three years without problems [87]. Clearly, these case reports do not prove cause and effect, and Izzo and Ernst [1] cite clinical trials that do not substantiate these observations. Isolated cases of unwanted effects in patients taking ginkgo and trazodone [88] and phenytoin and valproic acid [89] have been reported but have not been confirmed by further research.

8.4.5 Ginseng

Ginseng is the root of the *Panax* genus of plant and has been used particularly in the Far East for a variety of ailments and medical conditions including cancer prevention, the enhancement of cognition, cardiovascular disease, and hepatotoxicity [90]. Ginseng appears to have little or no effect on the activity of individual CYP enzymes [69].

In two case reports, self-medication with ginseng was associated with a decrease in INR in patients stabilized on warfarin [91,92]. In a placebo-controlled study in healthy subjects taking warfarin (5 mg/day for five days), a small decrease in the INR of 0.16 was observed, compared with a nonsignificant reduction of 0.02 in the placebo group [93]. A small decrease in the AUC of warfarin was also reported. However, in another study ginseng (3 g/day for two weeks) did not affect the pharmacokinetics or pharmacodynamics of a single 25-mg dose of warfarin in healthy subjects [48].

Two patients taking phenelzine for depression experienced symptoms such as headache, insomnia, and irritability after self-medicating with ginseng [94,95]. One of these patients began taking ginseng again three years later and suffered similar symptoms [96], providing stronger evidence that ginseng was the cause of these CNS effects.

8.4.6 Kava

Kava (*Piper methysticum*) is a plant of the Western Pacific. Preparations of its root are used to treat anxiety and insomnia [97]. Despite many reports that kava causes hepatotoxicity [98], it is still a widely used herbal remedy.

Kava has been shown to affect the *in vivo* activity of CYP2E1 but not those of CYP1A2, CYP2D6, or CYP3A [99] or PgP [100].

There is unconfirmed evidence that kava may enhance the CNS effects of alcohol [101]. In a single case report, a patient taking alprazolam, cimetidine, and terazosin was admitted to hospital in an agitated and disorientated state [102]. He admitted taking kava for the previous three days. The patient showed increased alertness after several hours. The authors suggested that kava may have supplemented the sedative effects of alprazolam. The pharmacokinetics of midazolam, a CYP3A4 substrate, appear to be unaffected by kava [99].

8.4.7 Milk Thistle (*Silybum marianum*)

Milk thistle in the form of tinctures and capsules has been used to prevent and treat liver damage, and may have anticancer, antidiabetic, and cardioprotective effects [103]. Milk thistle was shown not to affect the activities of CYP1A2, CYP2D6, CYP2E1, CYP3A4 [64], or PgP [104]. Two of the constituents of milk thistle, silymarin and silibinin, have been found to inhibit the *in vitro* activity of CYP2C9 using warfarin as a substrate, at concentrations that are believed to be clinically achievable [105]. The authors recommend a clinical evaluation of a potential milk thistle/warfarin interaction. The effect of milk thistle on the pharmacokinetics and pharmacodynamics of a number of other drugs has been studied, but no clinically significant effects have been identified [2,8].

8.5 DRUG–FOOD/FOOD CONSTITUENT INTERACTIONS

8.5.1 Food

A large number of interactions have been attributed to the effect of food through changes in drug absorption [5,106]. Interactions may be influenced by the amount and nature of the food eaten, as well as the time of drug intake in relation to the meal. Effects can occur through changes in gastric acidity, gastrointestinal motility, bile secretion, or chelation of a drug by a food constituent. Food high in fat can increase the bioavailability of lipophilic drugs, and in contrast food with high fiber content can decrease bioavailability in some cases.

A pivotal set of interactions involving nonselective monoamine oxidase inhibitor antidepressants and tyramine-rich foods, such as cheese, caviar, and pickled herring, was identified in the 1960s [107]. Patients suffered with potentially life threatening increase in blood pressure, which was sometimes accompanied by headache, flushing, sweating, and nausea and vomiting. In a series of early cases, tranylcypromine and phenelzine were most frequently implicated [107]. Under normal conditions, tyramine is metabolized in the gut and liver by monoamine oxidase. However, nonselective monoamine oxidase inhibitors block this activity, allowing absorption of tyramine, which causes vasoconstriction leading to increased blood pressure.

Another group of well-established and clinically important drug interactions occur through the consumption of dairy products and other foods along with the tetracycline antibacterials. Calcium ions present in milk, for example, chelate with tetracyclines forming complexes that are much less well absorbed from the gastrointestinal tract than the parent drugs. In one representative study, the consumption of homogenized milk decreased the absorption of tetracycline by 65% in healthy subjects, leading to a corresponding reduction on plasma drug concentrations [108]. The normal recommendation is that tetracyclines should be taken at least 1 h before or 2 h after food.

A comprehensive discussion and extensive lists of individual food–drug interactions can found in reviews by Schmidt and Dalhoff [106] and Baxter [5].

8.5.2 Grapefruit Juice

What has been commonly termed the *grapefruit juice effect* was discovered through a serendipitous finding, from a study investigating the interaction between the calcium channel antagonist felodipine and ethanol [109]. From a range of fruit juices, white double-strength grapefruit juice was chosen to mask the taste of ethanol. The combination of grapefruit juice alone and felodipine was associated with higher plasma felodipine concentrations, a lower standing blood pressure and a higher frequency of orthostatic hypertension compared to previous studies with felodipine alone. In a subsequent pilot study of a single subject, plasma concentrations of felodipine were more than five times higher with grapefruit juice than with water [110] (Fig. 8.2). A further study of six subjects with borderline hypertension, who had taken a single 5 mg oral dose of felodipine with water, grapefruit juice, or orange juice, demonstrated that grapefruit juice increased the bioavailability of the drug by 284% compared with water [111]. This was accompanied by a lower blood pressure and higher heart rate. No change in the elimination half-life of nifedipine was observed. Orange juice did not affect the pharmacokinetics or pharmacodynamics of nifedipine.

Figure 8.2 Plasma felodipine concentration–time profile from the pilot study in one subject. Felodipine as 5 mg regular tablet was administered with 350 mL double-strength grapefruit juice (■) or water (□). *Source:* From Bailey *et al.*, 1998; with permission.

Drug interactions with grapefruit juice occur after a single ingestion [112], and there is evidence that the effect is dose dependent [113]. An investigation of the duration of effect of grapefruit juice showed that the extent of the interaction declined slowly with time with a half-life of 12 h [114]. In addition, the magnitude of the interaction may vary according to the source and preparation of the juice [110].

A lack of effect of grapefruit juice on the pharmacokinetics of intravenous nifedipine suggested that the interaction occurs as a result of inhibition of the presystemic metabolism of nifedipine in the small intestine [112]. This hypothesis was supported by other studies investigating the effect of grapefruit juice on the intravenous and oral pharmacokinetics of midazolam [115], nifedipine [116], and nicardipine [117]. Nifedipine is a substrate of CYP3A4/5 [110], indicating that this enzyme is inhibited by grapefruit juice. Overall, grapefruit juice has been found to interact only with those drugs exhibiting high intestinal presystemic elimination.

Lown *et al.* [113] reported that administration of grapefruit juice to healthy subjects resulted in a 62% decrease in immunoreactive intestinal CYP3A4 and CYP3A5, without affecting CYP3A4 mRNA concentrations. However, grapefruit juice did not alter hepatic CYP3A4 activity, measured by the erythromycin breath test; colon concentrations of CYP3A5; and small bowel concentrations of PgP, villin, CYP1A1, or CYP2D6. It was concluded that grapefruit juice causes a downregulation of intestinal CYP3A but not hepatic CYP3A. The unchanged mRNA concentrations indicate that the decrease in CYP3A expression is unlikely to involve a reduced gene transcription or reduced stability of mRNA. Grapefruit juice is believed to exert its effects on intestinal CYP3A through mechanism-based inactivation by one or more components of the juice [118]. The activity of CYP3A has been shown to recover to preinteraction values after three days, which is compatible with enzyme regeneration after mechanism-based inhibition [119].

Early evidence suggested that grapefruit juice has a stimulatory effect on the transport of PgP substrates [120], possible counteracting its effect on intestinal CYP3A4. However, most evidence points to an inhibitory effect of grapefruit juice

on PgP activity [121]. Furthermore, the *in vitro* inhibition of a number of organic anion transporter polypeptides by grapefruit and other juices has been reported [121]. This suggests that drug bioavailability is decreased by inhibition of intestinal uptake transporters by fruit juices.

Much research has been directed to the identification of the constituents of grapefruit juice that cause this interaction [110], which was first attributed to the action of naringin, a flavonoid present in high concentrations in grapefruit juice [122]. However, subsequent studies in which pure naringin was administered to healthy subjects did not reproduce the effects seen with grapefruit juice [123]. It now seems more likely that other flavonoids, particularly, derivatives of the furanocoumarin bergamottin are responsible for the interaction [110]. For example, a range of dimers of 6',7'-dihydroxybergamottin have been shown to be highly potent inhibitors of gut CYP3A4 *in vitro* [124,125].

In addition to their effects on CYP3A activity, furanocoumarins have been found to inhibit CYP1A2, CYP1B1, CYP2A6, CYP2C9, CYP2C19, and CYP2D6, but were generally much less potent inhibitors of these enzymes than of CYP3A [124,126,127]. Grapefruit juice interactions mediated by CYP isoforms other than CYP3A are probably unlikely because they are not expressed or are expressed at low levels in the small intestine [128].

The effect of other fruit juices on drug disposition has been comprehensively reviewed by Farkas and Greenblatt [129]. Of the juices studied, which include orange, pomelo, lime, lemon, apple, cranberry, pomegranate, and grape, only grapefruit juice appears to show a consistent effect on the human pharmacokinetics of CYP3A substrates. However, Seville orange juice increased the AUC of felodipine to about the same extent as grapefruit juice [130]. Resveratrol, a compound found in high concentrations in red wine [131], was shown to inhibit human recombinant CYP1A1, CYP1B1, and CYP1A2 [132]. Furthermore, evaporated red wine (but not white wine) reconstituted in buffer caused inhibition of CYP3A4 and CYP2E1 in human liver microsomes [133]. Had these findings been confirmed *in vivo*, interactions with red wine could be of important clinical significance given the widespread consumption of this alcoholic beverage. However, subsequent studies showed that red wine does not affect the AUC of cisapride and felodipine [123,134]. On the other hand, red wine produced “dose dumping” in half the subjects in the felodipine study, causing a rapid increase in the plasma concentrations (but no change in the AUC) of the drug given as an extended release tablet [123]. It was suggested that the alcohol in red wine may have rapidly dissolved the tablet coating, leading to accelerated absorption of felodipine.

The following is a summary of the important interactions with grapefruit juice (and where relevant other juices). Emphasis is placed on those interactions that are clinically significant or potentially clinically significant, or involving drugs with a low therapeutic index.

8.5.2.1 Cardiovascular Drugs. Orange juice (200 ml) given three times daily to healthy subjects decreased the AUC of single-dose atenolol, a widely used β -blocker, by 40% [135] (Fig. 8.3). The authors suggested that impairment of transporters in the intestinal wall and/or of paracellular permeation of atenolol might contribute to this interaction, which they believed to be clinically significant. There are no published studies investigating the effect of grapefruit juice on the disposition of atenolol. The

Figure 8.3 Plasma concentrations (mean values $\pm$ SEM) of atenolol in 10 healthy subjects after a single oral dose of 50 mg atenolol; after ingestion of 200 mL orange juice (*solid circles*) or water (*open circles*) three times a day for three days; and on day 3 1 h before, with atenolol and 4 h and 10 h after atenolol administration. In addition, 200 mL orange juice or water was ingested at 08:00 and 13:00 h on day 4. Source: From Lilja *et al.*, 2005; with permission.

effect of grapefruit juice on the pharmacokinetics of other much less widely used β -blockers has been reviewed by Baxter [5].

The bioavailabilities of the calcium channel antagonists, felodipine, nicardipine, nifedipine, nimodipine, and nitrendipine, are all increased by drinking grapefruit juice [110]. A two- to threefold increase was observed for felodipine [111], and was associated with a decrease in diastolic blood pressure and an increase in heart rate. The severity of adverse effects such as headaches, facial flushing, and lightheadedness was also enhanced. Although increased bioavailabilities of the other dihydropyridines were observed, grapefruit juice caused only minor changes in hemodynamics. Probably, because it possesses high bioavailability, the pharmacokinetics of amlodipine was affected to a much smaller extent by grapefruit juice [136]. The effects of grapefruit juice on the pharmacodynamics of the dihydropyridine calcium channel antagonists vary, but it is probably advisable to avoid the combination, particularly, in the case of felodipine.

Grapefruit juice was shown to have no [137] or little effect (a 20% increase in the AUC) on the pharmacokinetics of the calcium channel antagonists diltiazem or on blood pressure or heart rate [138].

The AUC of the calcium channel antagonist, verapamil, was increased by a mean of 45% in subjects who drank grapefruit juice daily for three days [139]. A small increase, which was of borderline statistical significance, in the PR interval was observed. In a study of healthy subjects, grapefruit juice consumed two to four times daily for three to four days increased the AUC of verapamil by about 30%, but had no effect on its pharmacodynamics [140]. A recent case of severe toxicity in a grapefruit juice

consumer who had accidentally taken three tablets of verapamil (120 mg each) [141] further suggests that this interaction may be clinically significant.

Overall, grapefruit juice appears to have little effect on the pharmacokinetics of digoxin, a substrate of PgP. However, in one study, the plasma concentrations of the drug increased by 50% in two subjects, and this was associated with asymptomatic changes in the ECG (electrocardiography) [142]. Such an interaction should be considered if unexpected responses to digoxin are observed.

Elevated plasma concentrations of the statins increase the risk of adverse effects (muscular pain and more seriously rhabdomyolysis). Grapefruit juice has a substantial effect on the pharmacokinetics of atorvastatin, lovastatin, and simvastatin, which are all substrates of CYP3A4 [143]. A 2.5- and 1.5-fold increase in the AUC of atorvastatin acid and total HMG-CoA reductase inhibitors, respectively, were observed in healthy subjects given double-strength grapefruit juice for five days and a single 40-mg dose of atorvastatin on day 3 [144]. Two further studies confirmed these findings [145,146]. Double-strength grapefruit juice given for three days and then at the same time as a 80-mg single dose of lovastatin increased the AUC of the latter and its active metabolite, lovastatin acid, by 15- and 5-fold, respectively [147]. Pretreatment with as little as 200 mL of normal strength grapefruit juice increased the AUCs of simvastatin, given as a single 40 mg oral dose, and simvastatin acid by 3.6- and 3.3-fold, respectively [148] (Fig. 8.4). Rhabdomyolysis was reported in a single patient taking simvastatin 80 mg/day, and who had begun eating grapefruit daily for the previous four days [149]. On the other hand, grapefruit juice does not appear to affect the pharmacokinetics of pravastatin, which is not metabolized by CYP3A4 [144]. These data, particularly for lovastatin and simvastatin, suggest that patients should be made aware of the risks of consuming grapefruit juice while taking statins.

Grapefruit juice and pomegranate juice may increase the INR of warfarin [150,151], but further research is needed to confirm these findings. Baxter [152] has reviewed the controversial interaction between warfarin and cranberry juice, citing a number of cases of elevated INR values, one of which was fatal. However, based on a systematic review of the published literature, Zikria *et al.* [153] have questioned the importance of this interaction, based on the paucity of scientific evidence. Lilja *et al.* [154] have shown that daily ingestion of cranberry juice barely affected the pharmacokinetics of warfarin, indicating that a pharmacokinetic mechanism for this interaction seems unlikely.

8.5.2.2 Drugs Affecting the CNS. The effects of grapefruit juice on the plasma concentrations of the tricyclic antidepressants, amitriptyline and clomipramine, appear to be minimal [155].

Grapefruit juice has been shown to increase the plasma concentrations of the SSRI antidepressants, fluvoxamine and sertraline, by 50% and 33%, respectively [156,157]. In a single case report, it was suggested that grapefruit eaten in excessive amounts by a patient taking fluoxetine may have caused serotonin syndromelike symptoms [158].

In epileptic patients taking daily carbamazepine, which is metabolized mainly by CYP3A4, a single 300 mL drink of grapefruit juice increased the AUC of the drug by 40% [159]. The authors suggest that grapefruit juice should be avoided in patients taking carbamazepine, a recommendation supported by a single case report of a patient experiencing CNS toxicity accompanied by elevated drug concentrations when taking carbamazepine and eating one grapefruit per day [160].

Figure 8.4 Mean plasma concentrations of (a) simvastatin and (b) simvastatin acid after administration of a single 40-mg dose of simvastatin with 200 mL water (control) (○) or grapefruit juice (●) ingested once daily for three days. *Source:* From Lilja *et al.*, 2004; with permission.

Grapefruit does not affect the pharmacokinetics of the antipsychotic drug clozapine, a substrate of CYP1A2 [161], or of halofantrine [162].

The AUC of a single dose of the benzodiazepine diazepam was increased by three-fold in healthy subjects who drank 250 mL of grapefruit juice [163]. The effect on the pharmacodynamics of diazepam was not evaluated. A single 250 mL drink of grapefruit juice increased the AUC of oral midazolam by 52% and enhanced its pharmacodynamic effects [115]. In contrast, the clearance of oral or intravenous midazolam was

not impaired by pomegranate juice [164]. A 50% increase in the AUC of oral triazolam was observed in subjects who drank 250 mL of grapefruit juice, and this was accompanied by a small increase in drowsiness and sedation [165].

Grapefruit juice has been shown not to enhance the pharmacodynamic effects of caffeine, although a slight decrease in its clearance has been observed [166,167].

Only small changes in the pharmacokinetics of opiates have been observed when taken with grapefruit juice. For example, a 17% increase in the AUC of methadone, a CYP3A substrate, was reported when 200 mL of grapefruit was drunk 30 min before and at the same time as the drug was taken [168].

8.5.2.3 Immunosuppressive Drugs. Cyclosporin, which is predominantly metabolized by CYP3A, has a narrow therapeutic range, and elevated plasma drug concentrations may lead to nephrotoxicity. There has been considerable research on the influence of grapefruit juice on the pharmacokinetics of this drug [1,169], and trials have shown that the bioavailability of cyclosporin is substantially increased by the juice. In a representative study, 10 medically stable transplant patients were given 175 mL of grapefruit juice or water for one week at the same time as their daily cyclosporin therapy [170]. Grapefruit juice increased the AUC and trough plasma concentration of cyclosporin by 34% and 77%, respectively. This established interaction is likely to be clinically significant, and grapefruit juice and cyclosporine should not be taken together. Because of the high cost of cyclosporin, it has been suggested that grapefruit juice should be coingested on economic grounds to reduce the dose of the former [171]. However, this view has been challenged [172]. Because of the considerable variability in the interaction, caused by variability in cyclosporin pharmacokinetics and in grapefruit juice batches, consistent plasma cyclosporine concentrations may be difficult if not impossible to achieve.

Similar findings have been reported for tacrolimus, another drug widely used to prevent organ rejection [169]. In one study, the whole blood trough concentrations of tacrolimus were doubled by ingestion of grapefruit juice daily for seven days in liver transplant patients [173]. Grapefruit juice has been shown to increase (by 75%) the plasma concentrations of methylprednisolone [174] but not those of prednisone or prednisolone [175].

8.5.2.4 HIV-Protease Inhibitors. The AUC of single-dose saquinavir, a substrate of CYP3A, was shown to be increased by 50% following ingestion of 400 mL of grapefruit juice [176], but this increase was not believed to be clinically significant. Grapefruit juice does not appear to affect the pharmacokinetics of indinavir [177].

8.5.2.5 Other Drugs. Ingestion of grapefruit juice is associated with small, clinically insignificant increases in the plasma concentrations of estradiol and ethinylestradiol, components of the oral contraceptive pill [178,179].

Tasseneeyakul *et al.* [180] reported a lack of effect of grapefruit juice on the AUC of the proton pump inhibitor omeprazole in healthy subjects.

Grapefruit juice was found to increase the AUC of single dose of the antibiotic erythromycin (which is mainly metabolized by CYP3A4) by 49% in healthy subjects [181]. It has been suggested that the combination might lead to even larger increases in plasma concentration in patients who regularly consume grapefruit juice, resulting from greater inhibition of CYP3A4 [182].

Grapefruit juice was found to increase the AUC of single-dose sildenafil, a drug used to treat erectile dysfunction, by 23% in healthy subjects [183]. The authors of this study advise that, although the risks of adverse effects are small, patients should avoid this combination.

8.5.3 Green Tea

Green tea is made from the leaves of the *Camellia sinensis* plant. There is equivocal evidence that it can reduce the risks of cancer and cardiovascular disease and there are claims for other health benefits [184]. There is conflicting evidence that green tea can inhibit the activities of CYP enzymes [2], and no clinical interactions have been identified based on this mechanism.

8.5.4 Licorice

Licorice is an extract of the root *Glycyrrhiza glabra* and is used as a sweetening and flavoring agent. It has been taken to treat a range of medical conditions including gastritis and upper respiratory tract infections [185]. The main active constituent of licorice is glycyrrhizic acid. There is contradictory evidence that licorice can inhibit the activities of the CYP enzymes [2]. The lack of effect of aqueous licorice extract on the pharmacokinetics and sedative effects of midazolam, a probe substrate for CYP3A4, indicates that licorice did not influence the activity of this enzyme [186]. On the other hand, oral dosing with glycyrrhizin has been shown to increase the AUC of prednisolone [187], which is a substrate of CYP3A4 [188]. In a more recent study, the AUC of omeprazole was slightly decreased by glycyrrhizin, possibly through induction of CYP3A4 [189].

8.6 CONCLUSIONS

There is a large body of research on herb–drug and food/food constituent–drug interactions, particularly, those involving St. John’s wort and grapefruit juice, and knowledge is increasing rapidly. Many of these interactions occur as a result of changes in the activities of the CYP enzymes and transporter proteins such as PgP. A number of clinically significant interactions have been identified, which can have serious consequences. However, much of the published evidence is based on case reports or on pharmacokinetic data alone, and these require substantiation by studies measuring the clinical effects, of drugs. It is clear that the extent of herb–drug and food/food constituent–drug interaction show considerable interindividual variability, due in part to the wide variation in the activities of the CYP enzymes and transporter proteins. Research into interactions of this type is further limited by the characteristics of herbal and food products themselves. Many are composed of an intricate mix of bioactive compounds, which is likely to vary from batch to batch, and each may play a role in precipitating an interaction. Because herbal and food products are not regulated to the same extent and not subject to the same rigorous evaluation as therapeutic drugs, and because of the variability in the clinical effects produced, herb and food interactions are more difficult to document, characterize, and predict. It is essential that future research should be directed to the further characterization of the active constituents of

herb and food constituents and to the elucidation of their pharmacokinetics in humans. In conclusion, caution should be exercised in the consumption of herbal remedies and food with prescribed drugs, and health-care practitioners and patients should be made more aware of the potential risks of their concomitant use.

9.1 SUMMARY

Drug disposition in humans is influenced by its absorption, volume of distribution, metabolism, and, finally, its elimination. Drug metabolism involves phase I and phase II biotransformations, most of which occur in the human liver. Various physiological and pathological states may affect the hepatic metabolism of drugs. This chapter focuses on how physiological states may affect hepatic metabolism and the impact of liver disease on drug handling. The liver is vulnerable to a wide variety of insults, but the repertoire of its response to injury is limited. Likewise, the functional consequences of liver disease on drug disposition are determined by the extent of the injury, as opposed to its etiology. Although the liver's enormous functional reserve can mask the clinical impact of early liver damage, liver disease can ultimately produce multiple pathological consequences. Predicting drug metabolism in patients with liver disease is particularly challenging. No universal rule can be applied to the modification of drug dosages in patients with liver disease. Cirrhosis is the final common pathway for chronic liver disease. It has the propensity to affect drug metabolism more than any other form of liver disease. Unfortunately, there is little data available for patients with

severe liver disease, in whom pharmacokinetic and pharmacodynamic changes are most pronounced. Liver transplantation (LT) is the only curative option in patients with severe hepatic dysfunction or hepatic failure. Drug metabolism may also be altered in the liver transplant recipient. Herbal and alternative medicines are used as “liver remedies” in many patients with liver diseases, and their interactions with drugs and their potential to influence drug metabolism should also be considered in this patient group.

9.2 THE HUMAN LIVER AND DRUG METABOLISM

The liver is the largest internal organ in the body and is responsible for a wide variety of functions, including drug metabolism.

9.2.1 Liver Anatomy and Blood Supply

Blood flow to the human liver is unique, in that it receives a dual supply. The hepatic artery, a branch of the celiac artery, and the portal vein enter the liver via the porta hepatis. Both these vessels convey blood to the liver. The hepatic artery brings oxygenated blood to the liver, and the portal vein brings venous blood rich in the products of digestion, which have been absorbed from the gastrointestinal tract [1]. About 1100 mL of blood flows from the portal vein into the liver sinusoids each minute, and approximately an additional 350 mL flows into the sinusoids from the hepatic artery. This represents about 25% of resting cardiac output. Under normal circumstances, the portal vein supplies ~70% of the liver's blood supply and the hepatic artery is responsible for the remaining 30%. Blood from the hepatic artery and the portal vein perfuses the liver sinusoids and is conducted to the central vein of each liver lobule (Fig. 9.1). The pressure in the portal vein leading into the liver averages to about 9 mm Hg, and the pressure in the hepatic vein leading from the liver into the vena cava averages to 0 mm Hg. Hence, resistance to blood flow in the liver sinusoids is low, allowing for about 1.45 L of blood flow per minute under normal circumstances [2]. The central veins drain into the hepatic veins, which drain directly into the inferior vena cava.

The liver is made up of many liver lobules, which are the basic functional units of the liver. On average, an adult human liver contains 50,000–100,000 individual lobules.

Each liver lobule is centered around a central vein that empties into the hepatic veins (Fig. 9.2). The central vein (or terminal hepatic venule) of each lobule is a tributary of the hepatic veins. Functionally, however, hepatic “acini” are roughly a triangular portion of the liver lobule where the portal tracts form their bases and the central veins their apices [3]. The parenchyma of the hepatic acinus is divided into three zones (Fig. 9.1). Zone 1 is closest to the portal tract, while zone 3 is closest to the central vein and farthest from the portal tract. Zone 2 lies between zones 1 and 3. A lobular gradient of activity exists for many hepatic enzymes, which follow a zonal distribution [4]. As a result, many forms of hepatic injury also exhibit a zonal distribution.

The lobule itself is composed of many hepatic cellular “plates” seen microscopically as cords of cells that radiate from the central vein like spokes of a wheel. Each hepatic plate is one to two cells thick. The portal tracts, which lie between the hepatic lobules, contain the portal triad: branches of the hepatic artery, portal vein, and bile duct (Fig. 9.2). Between the “plates” or cords of the hepatocytes are vascular sinusoids.

even large plasma proteins can diffuse freely into the space of Disse. This also allows lipophilic drug molecules and its metabolites to readily diffuse into and out of the hepatocytes. However, polar compounds do not cross the lipid domain of the hepatic sinusoidal membrane readily, and carrier-mediated transport processes are required for this [6]. The spaces of Disse connect with lymphatic vessels in the interlobular septa. Excess fluid in these spaces is removed via the lymphatics.

9.2.2 Drug Metabolism in the Liver

Drug disposition in humans is influenced by its absorption, volume of distribution, metabolism, and, finally, its elimination.

Drug metabolism involves phase I and phase II biotransformations. Most phase I and phase II reactions occur in the human liver.

Phase I biotransformation consists of oxidation, reduction, or hydrolysis reactions. The microsomal mixed-function oxidase system is the main system responsible for oxidation and some reduction reactions. This membrane-bound system of the endoplasmic reticulum consists of two enzymes (cytochrome P450 and nicotinamide adenine dinucleotide phosphate (NADPH)-dependent cytochrome P450 reductase) and requires NADPH and molecular oxygen to function. The liver is the major site of cytochrome P450-mediated drug metabolism [7], although CYP450 can also be found in smaller amounts in extrahepatic tissue. In humans, numerous cytochrome P450 genes have been identified, but only a small number of encoded proteins contribute to drug metabolism, namely, the CYP1, CYP2, and CYP3 families. Together, they are involved in 80% of oxidative drug metabolism and account for close to 50% of overall elimination of commonly used drugs [7].

Phase II biotransformation conjugates the parent drug or its phase I metabolite to endogenous substrates such as glucuronic acid, sulfate, or glycine to render the compounds more hydrophilic for excretion. Methylation and acetylation are other phase II conjugation reactions. Phase II biotransformations mostly occur in the liver cytosol, with the exception of the endoplasmic reticulum membrane-bound uridinediphosphoglucuronate glucuronosyltransferases (UGTs).

Phase III reactions lead to the transport of drugs or their metabolites into bile. Biliary excretion is mediated by ATP-dependent transporters located in the bile canaliculi.

Further details on the enzyme systems involved in drug metabolism can be found in the volume titled *Review of Drug Metabolism and Interactions. Enzyme Systems Involved in Drug Metabolism and Interactions*, part titled *Enzyme Systems Involved in Drug Metabolism and Interactions in Animals and Humans* and on the human cytochrome P450 system in the chapter titled *CYP450 Enzymes in Drug Discovery and Development: An Overview* in this encyclopedia.

9.2.3 Hepatic Clearance

Hepatic clearance is the volume of blood perfusing into the liver that is cleared of drug per unit time. Factors that affect hepatic clearance include hepatic blood flow, the fraction of unbound drug, drug-metabolizing enzymes and their activity, and intrinsic clearance that would be observed in the absence of blood flow, biliary excretion, or enterohepatic circulation and protein-binding restrictions. Hepatic clearance is usually, although not always, a first-order process (e.g., phenytoin). In the single-compartment

hepatic clearance model, the entire liver is perceived to be one compartment. Drug concentrations reach the liver via hepatic artery and portal vein supply. By this theory, at steady state, intrahepatic drug concentrations are in equilibrium with drug concentrations in emerging hepatic venous blood. Intrinsic clearance is the ability of the liver to eliminate the fraction of unbound drug in the absence of hepatic blood flow limitations. Unlike in the assessment of renal function where the measurement of creatinine clearance can be used, there is no similar tool or gold standard in the assessment of hepatic clearance.

Hepatic clearance is restrictive for drugs that have a low extraction ratio ($E_H < 0.3$), as it is limited by protein binding and enzymatic activity rather than by hepatic blood flow. Hepatic metabolism of such drugs (e.g., chlordiazepoxide) is often the principal pathway of elimination, resulting in long elimination-phase half-lives. Hepatic clearance of these drugs can be broadly influenced by changes in their plasma protein bound fractions or by changes in hepatic drug-metabolizing enzymes (e.g., induction or inhibition) (Table 9.1). Any altered physiological or pathological factors that could influence these two factors would also alter hepatic clearance. For example, pregnancy reduces the concentration of plasma proteins and may alter protein binding of drugs or the concomitant use of other drugs may inhibit or induce metabolizing enzymes, which

CYP3A	
• Antimicrobials – Rifabutin – Rifampin – Rifapentine – Nafcillin • Anticonvulsants – Carbamazepine – Phenobarbital – Phenytoin • Anti-HIV agents – Efavirenz – Nevirapine • Others – Glucocorticoids – Pioglitazone – St John's wort	• Antimicrobials – Clarithromycin – Erythromycin – Doxycycline – Ciprofloxacin – Troleandomycin – Telithromycin – Fluconazole – Itraconazole – Miconazole – Ketoconazole – Voriconazole • Antiarrhythmic agents – Amiodarone – Diltiazem – Verapamil • Anti-HIV agents – Delavirdine – Indinavir – Ritonovir – Saquinavir – Nelfinavir • Others – Grapefruit juice – Fluvoxamine – Mifepristone – Nefazodone – Echinacea

would in turn influence the metabolism of such drugs. Hepatic clearance for restrictively metabolized drugs that have low protein binding would be less affected by changes in protein binding. If the drug is not highly bound, the hepatic clearance after drug administration depends primarily on the hepatic intrinsic clearance of unbound drug, regardless of the route of administration. Conversely, hepatic clearance is significantly increased in highly protein-bound drugs, which are restrictively metabolized when they are displaced from their protein binding sites. Hepatic clearance then depends on the extent of protein binding and the intrinsic clearance of the unbound drug. However, free drug concentrations at steady state will remain unchanged if there is no change in hepatic intrinsic clearance. As drug effects are related to their unbound concentrations, patients are at toxicity risk for only a brief period in pure displacement-type drug interactions and dose adjustments are not needed. Although alterations in protein binding would change total drug concentrations, unbound drug concentrations should remain constant if hepatic clearance of unbound drug is unchanged. Drug levels should be measured as unbound concentrations, rather than as total concentrations, in order to avoid inappropriate dose adjustments or increases in the clinical setting. If unbound drug concentrations remain unchanged, dosage adjustment may not be warranted. Hepatic disease and drug interactions that affect drug-metabolizing enzymes (e.g., by inhibition or induction) would alter the intrinsic clearance of restrictively eliminated drugs. Dosage adjustments for low extraction ratio drugs administered either intravenously or orally would be necessary only when hepatic disease or drug interactions alter the hepatic intrinsic clearance of unbound drug. Expectedly, changes in liver blood flow are not expected to significantly affect total or unbound concentrations of a low extraction drug. The hepatic clearance of these compounds is not rate limited by liver blood flow.

Conversely, hepatic clearance is nonrestrictive in drugs that have high extraction ratios ($E_H > 0.7$). As the liver can extract these drugs as rapidly as they are presented to the organ, hepatic clearance is rate limited by liver blood flow. These drugs (e.g., propranolol) that are efficiently extracted by the liver have short elimination-phase half-lives and are thus sensitive to changes in hepatic blood flow, which has a major effect on their hepatic clearance. Intravenous administration of drugs with high extraction ratios may require dosage adjustments when disease or drug-induced alterations in hepatic blood flow occur. Alterations in protein binding will not change total hepatic clearance for drugs that exhibit a high extraction ratio, but they rather change the hepatic clearance of unbound drug and alter unbound drug concentrations. Dosage adjustment may be necessary to maintain the same unbound drug concentrations, even though total drug concentrations remain constant. As mentioned previously, drug levels in the clinical setting should be measured as unbound concentrations rather than as total concentrations, and dose adjustments should be made based on unbound concentrations. Changes in the hepatic intrinsic clearance of unbound drug do not alter total or unbound concentrations of a high extraction ratio drug significantly after intravenous administration because their hepatic clearance is rate limited by liver blood flow. Orally administered nonrestrictively metabolized drugs have extensive first-pass metabolism, which reduces their bioavailability, where only a small fraction of the absorbed dose reaches the systemic circulation (e.g., propranolol). Theoretically, a small change in the first pass of efficiently extracted drugs may alter systemic bioavailability markedly. In general, oral doses of such drugs do not need adjustments in response to changes in hepatic blood flow.

Differential effects of reduced liver blood flow and decreased enzyme activity make it theoretically possible for the elimination of one drug to be abnormal, while another drug is handled virtually normally in liver disease.

The activity of several drug-metabolizing enzymes (e.g., cytochrome P450, *N*-acetyltransferase, thiopurine methyltransferase) is influenced by genetic polymorphisms or mutations, which may result in more rapid or slower drug metabolism than the average population. For details on the genetic influence on drug metabolism and disposition, refer to the chapter titled *Clinical Implications of CYP Induction-Mediated Drug–Drug Interactions* in this encyclopedia.

9.2.4 Bile Formation and Biliary Excretion

Hepatocytes secrete bile at a constant rate into the bile canaliculi, which drain into the interlobular bile ducts. Few drugs are excreted, unchanged, into bile. Bile excretion requires the substance to (i) cross the hepatic sinusoidal endothelium and (ii) cross both the luminal and canalicular membrane surfaces of the hepatocyte (Fig. 9.2). Efficacy of the active transport mechanisms that are required for passage across these two hepatocyte membrane surfaces is determined by the chemical structure, polarity, and molecular weight of the substance. Bile, an aqueous solution, favors excretion of more water-soluble polar compounds [8]. Larger polar compounds with a molecular weight of 500–600 Da are excreted in bile, whereas smaller compounds with a lower molecular weight are eliminated by the kidneys. Compounds that enhance bile production would stimulate the excretion of drugs eliminated by this route, while compounds that inhibit bile flow or production will decrease the excretion of such drugs [9]. Orally administered drugs can be extracted by the liver and excreted into bile to a greater degree than with intravenous administration. Interlobular bile ducts join together to form progressively larger ducts, the right and left hepatic ducts and, eventually, the common hepatic duct. The common hepatic duct and the cystic duct from the gallbladder form the common bile duct, which delivers bile to the duodenum. Drugs that are excreted via bile enter this enterohepatic circulation where they are excreted into the small intestine and are reabsorbed back into the portal system either as the parent drug or as its metabolite [8]. As the intestinal mucosa also possesses metabolizing enzymes, the compound that is excreted into bile may or may not be the same as that reabsorbed via the enterohepatic circulation. In other words, a drug's metabolite or conjugate may be excreted into bile but should be hydrolyzed or converted by gut enzymes before systemic reabsorption. This increases a drug's bioavailability and prolongs its elimination phase (e.g., ursodeoxycholic acid, benzodiazepines, digoxin). The enterohepatic circulation also increases the total exposure of the gut mucosa to drugs with potential gastrointestinal toxicity (e.g., NSAIDs).

9.2.5 Physiological Changes in Hepatic Drug Metabolism

9.2.5.1 The Young. Fetal and newborn livers generally have reduced xenobiotic metabolism capacity, even though detectable smooth endoplasmic reticulum and monooxygenase activity have been found as early as the week 6 of gestation [10–13]. Multiple studies have been performed to evaluate P450 content of the liver, but there have been no direct studies evaluating the effects of hepatic blood flow on infants.

Although cytochrome P450 enzymes have been isolated from fetal liver [14], antibody [15–17] and mRNA [18] analyses confirm that it lacks most adult forms of P450. CYP3A7, and to a lesser extent, CYP1A1 predominate in fetal liver but are mostly absent in adult liver [19,20]. Other phase I enzymes present in fetal liver include flavin-containing monooxygenases that increase rapidly during fetal development [21]. Human fetal liver also has phase II GSH transferase activity [22,23], which is present mainly as an acidic isoform that declines with fetal development and is only weakly expressed at birth. The adult enzyme exists in several basic forms instead [24]. However, a rapid turnover results in low GSH levels in the fetal liver [25].

Newborns have ~30% of the adult levels of cytochrome P450. The activities of these enzymes rise two to three times over adult levels the first month after birth and remain high for several years [11,12]. Although there is interindividual and interenzyme variability in the development of hepatic enzymes, they approach at least adult levels by the first year of life. The capacity to metabolize CYP3A4 substrates is reduced below the age of 15 years, and this is especially pronounced in infants below 3 months of age [26]. Flavin-containing monooxygenases are present in the neonatal liver, mainly in the form of FMO1 and, to a lesser extent, FMO4, unlike adult human liver that contains the forms FMO3, FMO4, and FMO5 [27]. The capacity of some phase II reactions is also lower at birth. For example, delayed development of glucuronyl transferase may play a role in the pathogenesis of physiological neonatal jaundice [28,29]. Acetaminophen is predominantly cleared by glucuronidation in adults but instead by sulfation in neonates and young children.

Ontogeny and drug metabolism in the young are covered in greater detail in the chapters titled *Idiosyncratic Drug Reactions* and *Drug Metabolism and Interactions in Pediatric Patients* in this encyclopedia.

9.2.5.2 The Elderly. Elderly patients are also more likely to be on polypharmacy, increasing their risk of drug–drug interactions or drug–enzyme interactions.

The plasma half-lives of drugs are generally increased in old age [30]. Possible explanations include changes in the volume of distribution, decreased hepatic blood flow, decreased rates of drug metabolism, and decreased renal clearance [30]. The result of this decrease in drug biotransformation is decreased metabolic clearance and increased exposure of the individual to the drug at a given dose. This may predispose the elderly to medication toxicity and even hepatotoxicity with hepatotoxins.

Phase I biotransformations catalyzed by CYP3A in the elderly have most consistently been shown to be decreased, by up to 40%. Prototype CYP3A substrates that exemplify this are midazolam and triazolam [31,32]. Hence, older patients treated with a given dose of triazolam will experience increased sedative effects [33]. It is unknown if CYP3A activity in the gastrointestinal mucosa is affected by aging as well [34]. However, some studies of human tissue have not demonstrated age-related reductions in the levels of NADPH P450 reductase, cytochrome P450 isoforms 3A2 and 2C8, or glutathione [35,36], suggesting that P450 declines with age may be restricted to only certain forms. A decline in P450 forms 1A2 and 2C with advancing age has been reported in humans, regardless of gender [37]. Modest decreases in clearance of warfarin (CYP2C9), phenytoin (CYP2C19), theophylline (CYP1A2), and caffeine (CYP1A2) have been reported in older individuals [38–41].

Age does not affect the frequency of genetic polymorphism in hepatic enzymes.

Enzyme induction is generally considered to be normal in the elderly [30]. However, the enzyme induction by rifampicin and cigarette smoking that is seen in younger adults is not seen in the elderly. This suggests that enzyme induction may be impaired in the elderly, although this has not been a consistent finding.

Age has not been shown to alter phase II biotransformations. Prototype substrates studied include lorazepam (glucuronidation), oxazepam (glucuronidation), isoniazid (acetylation), procainamide (acetylation), and acetaminophen (sulfation) [42].

9.2.5.3 Nutritional Status. Nutritional deficiencies [43] and severe malnutrition can have major effects on drug metabolism [44]. Short fasting periods of up to seven days have not been shown to affect the metabolic clearance of most drugs [45]. However, theophylline clearance, which is dependent on CYP1A2, is reduced by a protein-deficient diet [43]. Another exception is glutathione *S*-transferase reactions that may be decreased with fasting, as demonstrated in rat studies [46] and human subjects with anorexia nervosa [47]. Malnutrition is also known to deplete glutathione stores and this may have important clinical implications. For example, such patients would be at greater risk of acetaminophen hepatotoxicity from metabolism via the CYP2E1 pathway, forming the toxic metabolite *N*-acetyl-*p*-benzoquinoneimine.

9.2.5.4 Pregnancy. Hormonal changes during pregnancy involve marked increases in a woman's estradiol and progesterone levels [48–50]. These changes can affect hepatic enzymatic activity and, consequently, drug elimination clearance.

Some phase I (i.e., CYP1A2) and II activities (i.e., *N*-acetyltransferase) have been found to be reduced in late pregnancy [51,52]. Caffeine elimination via CYP1A2 is decreased by half by midgestation and by three times by the third trimester as compared to the postpartum period [53]. Intrinsic hepatic clearance of theophylline via CYP1A2 is also reduced during pregnancy. However, its associated decrease in drug binding to plasma proteins during pregnancy results in less of a change in its hepatic clearance [54]. Furthermore, as a result of the changes in both the renal and hepatic clearance, the total elimination clearance of theophylline is unchanged in the third trimester of pregnancy. A population-based study has demonstrated that CYP2C19-dependent clearance of proguanil (an antimalarial) decreased by 50% [55]. The ratio of proguanil to cycloguanil (active metabolite of proguanil) is increased by as much as 60% during pregnancy due to this decreased metabolism [56]. Phase II caffeine metabolism via *N*-acetyltransferase has been demonstrated to decrease with pregnancy, as compared to the normal healthy nonpregnant state [52,57].

In contrast, other forms of P450 (i.e., CYP3A4, CYP2D6) may be induced [58,59]. Both estradiol and progestins have been found to activate the human orphan nuclear pregnane X receptor (PXR), which forms a heterodimer complex with the 9-*cis*-retinoic acid receptor (RXR). This heterodimer complex binds to the promoter region of the CYP3A4 gene and mediates its transcription [60,61]. The hepatic clearance of phenytoin (via CYP2C9) increases during pregnancy, resulting in correspondingly lower total plasma concentrations [62]. Decreased drug protein binding results in constant free plasma concentrations of phenytoin until late pregnancy when its intrinsic clearance increases [63,64]. Multiple studies have confirmed that CYP3A4 activity increases in pregnancy. Midazolam is exclusively eliminated by CYP3A4 metabolism [65,66] and is a recognized marker of CYP3A4 activity [67,68]. At term, the clearance of midazolam has been shown to be 2.9-fold greater in pregnant women [69]. The metabolic

clearances of cortisol [70], nifedipine [71], extended-release metronidazole [72], and methadone [73], all CYP3A4 substrates, have also been shown to be increased during pregnancy.

Lamotrigine (metabolized by glucuronidation) clearance has been shown to increase by >50% in pregnancy, necessitating dose adjustment [74]. Betamethasone (metabolized by glucuronidation) clearance has also been shown to be increased in pregnancy, and this increase has been demonstrated to be greater in twin than in singleton gestations [75].

CYP2D6 isoforms may be increased or decreased in pregnancy. CYP2D6 activity is increased during pregnancy in individuals who are homozygous and heterozygous extensive metabolizers. However, enzyme activity is decreased in homozygous poor metabolizers [76].

Serum concentration of some proteins (though not all) are altered during pregnancy. There is a decrease in albumin concentration, which is likely due to reduced albumin synthesis or increased albumin clearance. The reduction in albumin concentration can potentially alter the binding of drugs (e.g., theophylline) commonly bound to serum albumin, whereas total protein and α_1 -acid glycoprotein concentrations remain unchanged in pregnancy [77,78].

After delivery, pharmacokinetic values return to near normal values within days to weeks for most drugs.

Further details on metabolism and drug–drug interactions in pregnancy are covered in the chapter titled *Influence of Changes in Physiology, Transporters, and Enzyme Expression on Disposition and Metabolism of Drugs during Pregnancy and Clinical Implications* in this encyclopedia.

9.3 LIVER DISEASE AND DRUG METABOLISM

The liver is vulnerable to a wide variety of insults, but the repertoire of its response to injury is limited. Regardless of cause, five general responses are seen: hepatocyte degeneration, necrosis or apoptosis, inflammation, regeneration, and fibrosis. Likewise, the functional consequences of liver disease on drug disposition are determined by the extent of the injury, as opposed to its etiology. Although the liver's enormous functional reserve can mask the clinical impact of early liver damage, liver disease can ultimately produce multiple pathological consequences.

Liver diseases may alter drug absorption, disposition, and pharmacology. Drug dosing in patients with liver disease requires the consideration of the nature and severity of the liver disease, hemodynamic factors, and the drug's pharmacokinetics. Predicting drug metabolism in patients with liver disease is challenging for a number of reasons. First, there is no test available that can correlate changes in drug metabolism with the degree of hepatic impairment. Second, pharmacokinetic or pharmacodynamic consequences of a particular disease may exhibit interindividual or even intraindividual variability. Third, various hepatic factors that influence drug metabolism may be independently or even codependently altered in liver disease. Thus, no universal rule can be applied to the modification of drug dosages in patients with liver disease. This is why it can be difficult to ascertain whether certain drugs in clinical trials have inherent hepatotoxicity and why this is discovered after some drugs have come into the market.

Biochemical "liver function" tests, which are routinely employed in the clinical setting, are surrogate markers of specific hepatic functions (e.g., serum albumin reflects

protein synthesis) or of pathologic conditions (e.g., serum aminotransferase elevation reflects hepatocyte damage). These tests indicate the potential for qualitative pharmacokinetic changes, although they lack sufficient discrimination to be consistent predictors of impaired drug metabolism [79].

9.3.1 Parenchymal Disease

The etiology of acute hepatitis is myriad, ranging from viruses to hepatotoxins to autoimmune or metabolic causes. The plasma half-lives of many drugs are prolonged in patients with parenchymal liver disease [80] as a result of reduced hepatic drug metabolism, which may be due to various causes apart from altered enzyme activity alone. For example, decreased availability of NADPH may be caused by altered cellular energy metabolism, cholestasis, altered hepatic blood flow, loss of hepatocyte volume, and so on. Directly assaying enzyme activity from biopsy specimens may help in identifying the primary contributing factors [81]. Studies have found the concentration levels of P450 in moderate degrees of hepatitis and compensated cirrhosis to be normal [82].

Studies of adult patients with acute hepatitis indicate that the changes in drug disposition are variable and related to the extent of damage incurred. Mild disease may have no alterations, while severe disease may have significant alterations in drug disposition.

In acute viral hepatitis, drug elimination is usually normal or only modestly impaired. Observed changes tend to be variable and related to the extent of hepatocellular damage incurred [83]. If the acute episode of hepatitis is short-lived, drug disposition can return to normal. As the acute disease resolves, drug disposition returns to normal and may do so before normalization of the biochemical liver function tests [84].

In acute drug-induced liver injury, however, altered drug metabolism can precipitate further injury as the elimination of other potentially toxic compounds is impaired. For example, the elimination phase of acetaminophen is significantly prolonged in patients with hepatotoxicity (mean, 5.8 h; range, 4.3–7.7 h) and in patients with hepatorenal toxicity (mean, 7.7 h; range, 4.3–13.9 h), as compared to patients without evidence of liver impairment (mean, 2.7 h) [85]. Fatal outcome has been associated with acetaminophen elimination half-lives of more than 10 h.

Chronic liver disease may be caused by chronic viral hepatitis, autoimmune or metabolic causes, or chronic alcohol abuse. In alcoholic liver disease, fat accumulation within the hepatocyte leads to steatosis and overall hepatomegaly. Although cytochrome P450 content per weight tissue is decreased, drug metabolism is not impaired in early disease as this is compensated for by the increased liver size [86]. A study conducted in liver grafts discarded for transplantation because of >40% macrosteatosis demonstrated a reduction in microsomal P450 activities [87]. In chronic viral hepatitis, drug elimination may be impaired, although this usually occurs much later in the disease [88]. Patients with chronic viral hepatitis may also have extrahepatic involvement of disease, including glomerulonephritis with renal impairment [89–91]. In this case, drugs that depend on the kidneys for elimination will have a prolonged elimination half-life, increasing the body's exposure to the drug. Such drugs (e.g., nucleos[t]ide analogs used for chronic hepatitis B treatment) will need to be dose adjusted to the appropriate renal function.

Induction of P450 enzymes may be affected by liver disease. However, in mild hepatic disease and inactive cirrhosis, normal induction of P450 by drugs such as

phenobarbital, phenytoin, and glutethimide has been observed. Overall, changes in drug disposition tend to be less in acute hepatitis than in chronic liver disease [92].

9.3.2 Alcohol and Drug Metabolism

Chronic alcoholism is a common cause of liver disease, which may lead to abnormal drug disposition. Alcohol may alter drug absorption by changing its solubility, increasing intestinal blood flow, inhibiting gastric emptying, producing conformational changes in intestinal membranes, and affecting drug-metabolizing enzymes in the liver. In general, acute alcohol ingestion depresses, while chronic alcohol ingestion enhances, the rate of drug metabolism. The potential for pharmacokinetic drug interactions with alcohol is great because the same cytochrome P450 enzymes also metabolize many other drugs.

9.3.2.1 Acute Alcohol Ingestion. Acute alcohol ingestion may inhibit the activity of drug-metabolizing enzymes through different mechanisms.

First, alcohol may compete with the drug for the same microsomal system required for metabolism [93]. Drugs and alcohol may share a similar microsomal ethanol-oxidizing system. Acute alcohol ingestion inhibits this system, whereas chronic alcohol ingestion increases it [94,95]. Alcohol also inhibits cytochrome P450 reductase, a rate-limiting step in the oxidative biotransformation of drugs [96]. The breakdown and excretion of affected drugs are delayed because the drug must compete with alcohol for breakdown by cytochrome P450. This interaction has been described mostly for CYP2E1, but it may also involve CYP3A4 and CYP1A2 [97]. Second, alcohol may inhibit drug metabolism by competing with or displacing the other compound from its cytochrome P450 binding site [98], or indirectly decreases the availability of NADPH by inhibiting the citric acid cycle [99]. Third, alcohol induces the release of corticosterone that may also serve as an alternative substrate for the microsomal enzyme system, resulting in indirect inhibition of the drug-metabolizing system [100]. Fourth, alcohol may disturb the lipid bilayer membrane of the drug-metabolizing system, increasing the fluidity of hepatic microsomal membranes, causing a conformational change in the enzyme [101–103].

Alcohol also has an influence on phase II reactions. Acute alcohol ingestion impairs glucuronidation [104–107]. Intracellular nicotinamide adenine dinucleotide (NAD^+) and reduced NAD^+ (NADH) are needed for the function of many enzymes. Oxidative alcohol metabolism by alcohol dehydrogenase results in the conversion of NAD^+ into NADH, increasing the hepatocyte's NADH levels. Elevated NADH levels may stimulate steatosis and prevent the liver from generating UDP-glucuronic acid for conjugation. Heavy alcohol consumption reduces the amount of glutathione in liver cells, particularly in the mitochondria. Acute alcohol ingestion enhances acetylation by 20% [108].

9.3.2.2 Chronic Alcohol Ingestion. Chronic alcohol ingestion increases both microsomal mass [109] and activity of the monooxygenase system [110–113]. When alcohol is not present to simultaneously compete for the cytochromes, increased cytochrome activity results in an increased elimination rate for drugs metabolized by these enzymes. This may predispose a chronic alcoholic with acetaminophen overdose to hepatotoxicity via the formation of *N*-acetyl-*p*-benzoquinoneimine by the CYP2E1 pathway.

Chronic alcohol ingestion induces glucuronyl transferase [114] and its action of glucuronidation. The effect of chronic alcohol ingestion on acetylation has not been evaluated.

9.3.2.3 Pharmacodynamic Effects with Alcohol. The concomitant acute ingestion of ethanol and other agents with sedative action may result in greater psychomotor impairment than that produced by each agent independently. First, the more profound effect may simply reflect the combined action of both sedative drugs on the central nervous system. Second, the sedative compound may itself alter the metabolism of ethanol. For instance, chloral hydrate, which is metabolized to trichlorethanol by alcohol dehydrogenase, vies with ethanol for the same pathway and results in higher plasma concentrations of ethanol [115–117]. However, a number of other sedatives [118], including pentobarbital, meprobamate, and the benzodiazepines clobazam [119] and clorazepate [120], do not disturb the metabolism of ethanol. Third, ethanol may impair the degradation of other sedative compounds (e.g., lorazepam, diazepam).

9.3.2.4 Drug Disposition and Elimination with Alcohol

9.3.2.4.1 Benzodiazepines. Short-term alcohol ingestion diminishes the hepatic clearance of a number of widely used benzodiazepines [121–123], without an effect on drug binding or distribution. With impaired biotransformation of benzodiazepines, more drug may reach the cerebral receptor sites, resulting in a greater sedative effect. The effect of chronic alcohol ingestion on benzodiazepine metabolism is less well established. After chronic ethanol intake and during subsequent ethanol withdrawal, plasma concentrations on day 2 of withdrawal were higher than those on day 6 [124], which suggests decreased (not increased) drug elimination. Sellman *et al.* [125] showed that the plasma concentrations of diazepam after an oral dose were lower than those in control; this implies decreased absorption or increased clearance.

9.3.2.4.2 Chloral Hydrate. Chloral hydrate shares a common metabolic pathway with ethanol and is rapidly converted by alcohol dehydrogenase to trichlorethanol. Acute ethanol ingestion results in significantly higher levels of trichlorethanol and lower levels of its resultant glucuronide metabolite in the plasma and urine. In turn, the conversion of ethanol to acetylaldehyde is diminished and results in higher plasma ethanol concentrations [115]. These result in the greater sedative effect seen following combined alcohol and chloral hydrate administration.

9.3.3 Cholestatic Disease

Cholestasis may occur as a result of cellular transporter defects (such as mutations of transporter genes or acquired dysfunction of transport systems) or from biliary obstruction [126]. Bile salts not able to exit the hepatocyte in cholestasis are effectively removed across the basolateral membrane [127]. Studies have demonstrated up to 70% reduction of cytochrome P450 levels in liver biopsy specimens of subjects with obstructive liver disease, correlating with altered antipyrine clearance [128]. CYP1A2 and 2E1 have specifically been found to be reduced in cholestatic disease [129,130]. The findings in the setting of extrahepatic cholestasis have been conflicting. The elimination of drugs that are excreted mainly via bile is decreased in any cause of cholestasis

[9]. The bioavailability of such drugs is reduced due to the disruption of enterohepatic cycling.

Furthermore, drugs such as cholestyramine (frequently used in patients with liver disease such as primary biliary cirrhosis) that are bile sequestrants would interfere with the pharmacokinetics of drugs that undergo significant enterohepatic circulation. Conversely, the discontinuation of cholestyramine would potentiate drug toxicity (e.g., digitalis) if it had been titrated to a maintenance dose while the patient was taking cholestyramine. Cholestyramine also acts as an ion-exchange resin and reduces the absorption of concomitant oral medication such as warfarin, thiazide diuretics, propranolol, penicillin, phenobarbital, and digitalis.

9.3.4 Gilbert's Syndrome

Gilbert's syndrome is the most common inherited disorder of bilirubin glucuronidation. It has also been called *constitutional hepatic dysfunction* or *familial nonhemolytic jaundice* [131]. UGTs mediate the glucuronidation of various compounds. A mutation in the promoter region of the gene encoding bilirubin-UGT that conjugates bilirubin to glucuronic acid (UGT1A1) results in reduced production of bilirubin-UGT [132]. The inheritance of Gilbert's syndrome is most similar to that of an autosomal recessive trait.

As UGT1A1 is involved in the glucuronidation of estrogen, drugs, and carcinogens, individuals with Gilbert's syndrome may be more susceptible to the toxic effect of substances (e.g., acetaminophen, tolbutamide) that require UGT1A1-mediated hepatic glucuronidation before excretion [133,134]. Diminished drug excretion may cause their accumulation and increase toxicity. However, consequences of clinical significance have not been reported for most drugs. For example, intravenous, but not oral, administration of acetaminophen demonstrated reduced glucuronidation of the drug in subjects with Gilbert's syndrome [133,135,136]. While, the anticytotoxic agent irinotecan is glucuronidated in the liver mainly by bilirubin-UGT and excreted in bile. In subjects with UGT1A1 polymorphisms (e.g., Gilbert's and Crigler–Najjar syndrome), reduced glucuronidation of its active metabolite results in increased toxicity (e.g., diarrhea, severe neutropenia) [137–140].

Drugs that increase the hepatic uptake of bilirubin (e.g., corticosteroids), or hepatic enzyme inducers (e.g., phenobarbital, clofibrate), may reduce plasma bilirubin concentrations in patients with Gilbert's syndrome [141–144].

Unlike in Gilbert's syndrome where a defect in the promoter region results in reduced amounts of the normal protein produced, in Crigler–Najjar syndrome (autosomal recessive inheritance), mutations in UGT1A1 gene itself result in abnormal protein production, resulting in complete loss or severely low levels of UGT1A1 activity [145]. Crigler–Najjar syndrome type I was first described in 1952 [146]. It is usually diagnosed in infancy, and its clinical course is characterized by the development of progressive, permanent neurologic sequelae resembling kernicterus. Death usually occurs in the first two years of life. Patients who survive longer often have severe neurologic impairment [147,148]. Necropsy studies of such patients demonstrate massive bilirubin deposition in various organs, including the cerebral cortex and other structures of the central nervous system, and neuronal loss [146,149]. Total plasma bilirubin levels range from 15 to over 50 mg/dL. Type II disease is diagnosed later in childhood, and patients may survive into adulthood without permanent neurological impairment.

Further details and clinical relevance of the UGT enzymes are covered in the chapters titled *UDP-Glucuronosyltransferases: Pharmacogenetics, Functional Characterization, and Clinical Relevance* and *Role and Clinical Consequences of Human UDP-Glucuronosyltransferases* in this encyclopedia.

9.4 CIRRHOSIS AND DRUG METABOLISM

Cirrhosis is the final common pathway for chronic liver disease. It is characterized by the activation of fibroblasts and collagen deposition with nodular formation and resultant portal hypertension as the disease progresses.

There are several tools to stage the severity of liver cirrhosis, the most commonly used in clinical practice being the Child-Turcotte-Pugh (CTP) scoring [150,151], which ranges from a minimum score of 5 to a maximum score of 15 (Table 9.2). The Child-Pugh classification of disease severity is often used to make drug dosing recommendations for patients with cirrhosis [152]. However, it has several limitations, including poorer discrimination in early cirrhosis, a maximum cutoff score which scores all severe cirrhotic patients equally, and the fact that other factors apart from those included in the CTP scoring system may help to stratify the degree of hepatic impairment or its prognosis. The Model for End-Stage Liver Disease (MELD) [153] is a validated chronic liver disease severity scoring system [154,155], which incorporates the patient's serum bilirubin, serum creatinine, and the international normalized ratio for prothrombin time to predict survival. MELD has been modified slightly since its original development, eliminating negative scores and disease etiology. An increasing MELD score is associated with increasing severity of hepatic dysfunction and risk of death [156]. This model is also currently used by the United Network for Organ Sharing (UNOS) and in many transplant centers around the world in prioritizing allocation of deceased donor organs for LT. Several online calculators are available for ease of calculating the MELD score (e.g., <http://www.mayoclinic.org/meld/mayomodel6.html>. Accessed 5 May, 2010).

Unfortunately, most clinical trials only enroll patients with mild or moderate liver disease. Caution should be taken in extrapolating these findings to patients with liver diseases of different etiology or degrees of severity. Unfortunately, there is little data

TABLE 9.2 Child-Turcotte-Pugh Scoring in Liver Cirrhosis

Parameters	Points Assigned		
	1	2	3
Serum albumin (g/dL)	>3.5	2.8–3.5	<2.8
Serum bilirubin (mg/dL)	1–2	2–3	<3
Prothrombin time (seconds above control)	1–4	4–10	>10
Ascites	Absent	Slight	Moderate
Encephalopathy grade	0	1–2	3–4
Child-Turcotte-Pugh classification	A (mild)	B (moderate)	C (severe)
Total number of points	5–6	7–9	>9

available for patients with severe liver disease, in whom pharmacokinetic and pharmacodynamic changes would be the most pronounced.

Cirrhosis affects drug metabolism more than any other form of liver disease by various mechanisms, some of which are detailed below.

9.4.1 Vascular Architecture and Hepatic Blood Supply in Cirrhosis

Fibrosis is, generally, an irreversible consequence of hepatic damage. In the initial stages, fibrosis may develop around portal tracts or central venules, or it may be deposited directly within the space of Disse (Fig. 9.3). In the normal liver, interstitial collagens (types I and III) are concentrated in the portal tracts and around the central veins, while type IV collagen courses alongside the hepatocytes in the space of Disse. The central pathogenic process in cirrhosis is progressive fibrosis. In cirrhosis, types I and III collagen are deposited in the lobule, creating delicate or broad septal tracts. Activated hepatic stellate cells, which lie in the space of Disse, transform into myofibroblast-like cells and are the major source of excess collagen in cirrhosis. When collagen is deposited in the hepatic sinusoids [86], it forms a basement membrane devoid of microvilli along the sinusoidal surface of the hepatocyte. New vascular channels in the septa connecting the portal veins with the central veins, the altered sinusoidal membrane, and the collagen barrier between the hepatocyte and sinusoid all result in functional shunting of blood past the hepatocyte. Intrahepatic shunting thus results from intrahepatic vascular anastomoses that bypass hepatic sinusoids and from the functional sinusoidal barrier caused by collagen deposition. This shunting interferes significantly with the hepatic uptake of oxygen, plasma constituents, drugs, and metabolites. Anatomic and functional intrahepatic shunting averages 25% of total liver blood flow in normal subjects but is increased to 33% in patients with chronic viral hepatitis and to 52% in cirrhotic patients [157].

The deposition of fibrous bands also disrupts the normal hepatic vascular architecture, increasing vascular resistance and portal venous pressure. Transformation of stellate cells into myofibroblasts also increases vascular resistance within the liver parenchyma by tonic contraction, which constricts the sinusoidal vascular channels. The net outcome is a fibrotic, nodular liver in which delivery of blood to hepatocytes is severely compromised.

When extreme amounts of fibrous tissue develop within the liver structure, it causes destruction of the parenchymal cells and it eventually contracts around the blood vessels, impeding the flow of portal blood through the liver. Portal venous flow that accounts for 70% of the normal total liver blood flow is reduced [158], but in the early stages, this decrease is compensated for by an increase in hepatic arterial supply to maintain a normal hepatic blood supply despite chronic viral hepatitis or cirrhosis [157]. This highlights the unique and important feature of the liver's dual blood supply. This increased resistance to portal flow at the level of the sinusoids and compression of the central veins by perivenular fibrosis and expansile parenchymal nodules result in the portal hypertension of cirrhosis. Anastomoses between the arterial and portal systems in the fibrous bands also contribute to portal hypertension by imposing arterial pressure on the low pressure portal venous system [5]. The increased portal pressure results in the compensatory formation of portosystemic shunts. Common sites of portosystemic collaterals include, but are not limited to, the gastroesophageal junction, splenic hilum, and umbilicus. In a study of cirrhotic patients with bleeding esophageal

varices, an average of 70% of mesenteric and 95% of splenic blood flow was found to be diverted through extrahepatic shunts [159]. Portocaval shunting can impair the efficiency of hepatic extraction and reduce the extraction ratio of drugs.

9.4.2 First Pass and Bioavailability in Cirrhosis

The bioavailability of orally administered high extraction drugs in patients with cirrhosis may be increased significantly because of a decreased first-pass effect, especially in patients who exhibit significant portosystemic shunting with decreased intrinsic clearance [160]. Oral dosing of high extraction drugs will result in high plasma concentrations. Coupled with abnormal clearance from hepatic dysfunction, this may produce prolonged pharmacologic effects with potential toxic consequences. This may be dangerous, especially for drugs with a low therapeutic index. Propranolol [161,162], labetalol [163], lidocaine [164], salicylamide [165], meperidine [166], pentazocine [165,166], and nicardipine [160] are examples of drugs having markedly increased bioavailabilities when administered to cirrhotic patients.

The clearance of highly extracted drugs is more greatly affected in patients having a high degree of portosystemic shunting, whereas low extraction drugs are more sensitive to changes in intrinsic clearance [80,167]. As hepatic blood flow and perfusion are reduced in patients with advanced cirrhosis, hepatic clearance is reduced and the bioavailability is increased for highly extracted drugs to the extent that it no longer approximates hepatic blood flow but is influenced by hepatic intrinsic clearance instead [168]. This increased bioavailability, which is accompanied by decreased elimination for some drugs (e.g., propranolol [161,162]), further increases the body's exposure to the drug. Hence, portosystemic shunting and hepatocellular damage significantly increase the bioavailability of drugs that would normally have an extensive first pass. The clearance of high extraction drugs is more consistently decreased in chronic liver disease than that of low extraction drugs [167]. Portocaval shunting has less impact on drug bioavailability of restrictively metabolized drugs that have minimal first-pass metabolism even in normal subjects.

9.4.3 Protein Binding and Volume of Distribution in Cirrhosis

Cirrhotic patients have a hypoproteinemic and hypoalbuminemic state that may reduce drug binding to plasma proteins [169]. Also, bilirubin and bile acids accumulate in cirrhosis and may displace drugs from their protein binding sites. The volume of drugs, especially those that are highly protein bound (>90%), may be increased in patients with chronic liver disease who exhibit hypoalbuminemia or ascites [80,170,171].

For restrictively metabolized drugs, hepatic clearance is increased with reduced protein binding. The effect of hepatic clearance or metabolism of a drug in cirrhosis depends on the net result of changes for various factors. For example, liver disease may decrease the intrinsic clearance of drugs with low intrinsic clearance, which are highly protein bound, yet increase the fraction of unbound drug by reducing protein binding. However, unbound drug concentrations will not be affected by decreases in the protein binding of restrictively metabolized drugs. Therefore, no dosage alterations are required for these drugs if protein binding is the only parameter that is unchanged. Liver disease generally produces no change in warfarin clearance, decreases diazepam clearance, and increases tolbutamide clearance.

Conversely, for nonrestrictively metabolized drugs, reduced protein binding does not affect the clearance or total plasma concentration, but will increase the drug's free concentration. This potentially increases the pharmacological effects observed at a given total drug concentration [169]. For such drugs, reduced protein binding increases their distribution volume and, hence, their elimination-phase half-life and the time required to reach steady state. For example, cirrhosis reduces verapamil clearance by 50% yet increases the drug's volume of distribution, resulting in a significant increase in its half-life (from 3.7 to 14.2 h) [172]. This extends both the time to reach steady state and the time to eliminate the drug from 12 to 45 h. Such alterations in pharmacokinetics have also been described with lorazepam [173] and chloramphenicol [174] in cirrhotic patients. Therefore, in nonrestrictively metabolized drugs, a reduction in plasma protein binding necessitates a corresponding reduction in drug dosage.

9.4.4 Hepatic Enzymes in Cirrhosis

As cirrhosis progresses, extensive fibrosis causes a reduction in liver size, resulting in a marked reduction of total P450 concentrations [82,175,176]. This limits and decreases drug metabolism and hepatic clearance of most drugs. However, not all P450 activities are decreased uniformly in severe liver disease; for example, ethylmorphine demethylase activity is unaltered [177,178]. In the cirrhotic liver, the levels of CYP isoforms 1A2, 2E1, and 3A4 are reduced [130,179]. The clearance of *S*-mephenytoin, a CYP2C19 probe, was shown to be decreased by 63% in patients with mild cirrhosis and by 96% in patients with moderate cirrhosis, whereas debrisoquine clearance (CYP2D6 probe) was normal [180]. Although CYP2C activity is barely altered with hepatocellular disease, it has been shown to be markedly reduced in patients with cirrhosis due to cholestatic disease [130]. Commonly used drugs which may have altered metabolism in this setting include theophylline (CYP1A2), alcohol (CYP2E1), acetaminophen (CYP2E1), calcineurin inhibitors (CYP3A4), HMG-CoA reductase inhibitors (CYP3A4), and warfarin (CYP2C9). NADPH-cytochrome P450 reductase activity is normal even in severe liver disease [130].

However, P450 levels do not always correlate well with half-lives for the clearance of some drugs [177] and some commonly used drugs in cirrhotic patients should have their doses reduced by half (Table 9.3). Most of these drugs have high first-pass metabolism, which is markedly reduced with impaired liver function. Decreased elimination half-lives further increase drug exposure to standard doses. Active metabolite formation also complicates drug response and dose adjustments. For example, losartan has an active metabolite that is primarily responsible for the extent and duration of its pharmacological effects [181]. Standard doses of losartan in cirrhotic patients increase plasma concentrations of the parent drug by four to five times but increase the plasma concentration of its active metabolite by only 1.5–2 times [182,183].

Generally, the clearance of drugs that undergo only conjugation is not altered significantly in patients with severe liver disease, but this remains controversial [184,185]. Analysis of human liver biopsy specimens reveals minimal change in bilirubin-glucuronidating capacity in hepatitis or cirrhosis [186–188]. Although there is evidence that this pathway is compromised in severe liver disease [189], increased enzyme activity in remaining viable hepatocytes preserves overall glucuronidating capacity in cirrhotic patients [190]. Hence, drugs that only undergo glucuronidation for elimination (e.g., oxazepam and lorazepam) are unaffected by liver disease

TABLE 9.3 Common Drugs with Reduced Clearance in Cirrhotic Patients

β -Blockers	Anesthetics/sedatives
• Propranolol	• Diazepam
• Metoprolol	• Hexobarbital
Calcium channel blockers	• Chlordiazepoxide
• Verapamil	• Lidocaine
• Nifedipine	• Encainide
Antibiotics	• Morphine
• Chloramphenicol	• Tocainide
• Erythromycin	• Pentazocine
	• Meperidine
	Others
	• Acetaminophen
	• Caffeine/Theophylline
	• Omeprazole
	• Losartan
	• Antipyrine

[173,191,192]. However, studies have described well-preserved glucuronide conjugation of morphine in patients with compensated cirrhosis but a 59% reduction in decompensated cirrhotic patients with a history of hepatic encephalopathy [193,194].

9.4.5 Renal Impairment in Cirrhosis

Renal impairment is often underrecognized in the setting of cirrhosis. The fluid status in the clinical setting of cirrhosis is notoriously difficult to assess. Portal hypertension results in ascites and peripheral edema, akin to a hypervolemic state. However, this results in intravascular fluid depletion, resulting in an intravascular hypovolemic state instead. Elevated intra-abdominal pressure, as seen in ascitic patients, may influence central venous pressure measurements [195], which have also been shown to be of little value in assessing fluid responsiveness in critically ill patients [196–198]. Serum creatinine, which is the most commonly used marker of kidney injury, has diagnostic limitations. It lags behind renal injury and is a delayed marker of decreased renal function [199], it may be normal or only minimally elevated because of renal reserve or enhanced tubular secretion [200,201], and it is unable to distinguish between the various causes of kidney injury. It is also influenced by several nonrenal factors such as gender, age, race, body weight, drugs, muscle metabolism, and protein intake [200]. In the cirrhotic patient with low muscle mass, serum creatinine levels may be falsely low. Laboratories using the chemical (instead of enzymatic) method to measure serum creatinine levels result in falsely low readings in the presence of severe hyperbilirubinemia [202].

Cirrhotic patients are at risk of developing significant kidney injury for a number of reasons, including, but not limited to, prerenal azotemia and acute tubular necrosis from septicemia [203]. The hepatorenal syndrome occurs when vasodilatation of

the splanchnic circulation results in a relative “hypovolemic” state that activates pressor responses and causes marked vasoconstriction of the renal circulation [204]. This reduces renal perfusion and glomerular filtration rate significantly in these patients. The functional nature of this syndrome is reflected by its reversal following successful LT and the absence of significant renal damage on histology. The risk of developing hepatorenal syndrome in cirrhotic patients with ascites is 18% in one year and 39% in five years [205]. Drug metabolism is altered in such patients as the elimination-phase half-life would be prolonged for drugs excreted primarily by the kidneys [206–208]. Hence, drug dosages need to be adjusted correspondingly.

Cirrhotic patients may also be at increased risk of developing acute renal failure with potentially nephrotoxic drugs [209] (i.e., aminoglycosides and nonsteroidal anti-inflammatory drugs). The use of nephrotoxic drugs should be avoided or, at the very least, appropriately dose adjusted in cirrhotic patients.

9.4.6 Drug Response in Cirrhosis

Altered physiology in the state of cirrhosis may cause the body to respond differently to standard doses of drugs. Unfortunately, little is known about the pharmacodynamics of drugs in patients with hepatic dysfunction.

For example, standard doses of sedatives are known to precipitate hepatic encephalopathy in the cirrhotic patient. Studies have demonstrated both impaired drug metabolism and increased γ -aminobutyric acid-mediated inhibitory neurotransmission in hepatic encephalopathy, providing the basis for brain hypersensitivity and this exaggerated response to sedatives [210,211]. Encephalopathy has also been found to reverse with the administration of flumazenil, a benzodiazepine antagonist [211]. Central nervous system sensitivity is also increased with morphine [194,212], chlorpromazine, diazepam, and other sedatives, analgesics, and tranquilizers [210,213–215].

An empirical and cautious approach to medication use in liver patients should be guided by the clinical response and side effects and in some cases, plasma drug monitoring is recommended. As an initial dosing guideline, the dose of drugs eliminated by oxidative metabolism should be halved. In hepatic decompensation (e.g., ascites, encephalopathy), even lower doses may be used. Dose adjustments should be made based on therapeutic response or adverse effects. Drugs that are extensively metabolized before reaching the systemic circulation may be completely absorbed as parent drug in cirrhotic patients. Similarly, the first-pass effect may not exist in patients with a portocaval shunt [79].

More studies are required to evaluate the effects of liver disease on the pharmacokinetics and pharmacodynamic effects of drugs, especially those likely to be used in patients with hepatic dysfunction.

9.4.7 Anesthesia in Cirrhosis

Apart from increased perioperative risks arising from the hyperdynamic circulatory, altered fluid and coagulopathic status of the patient, the cirrhotic liver is also particularly susceptible to the effects of anesthetic drugs administered. Patients with liver disease may have altered drug pharmacokinetics because of increased volume of distribution, decreased cytochrome P450 enzyme metabolism, decreased serum drug binding due to low protein/albumin levels, and sometimes decreased biliary drug excretion.

The autoregulation of blood and oxygen supply to the liver between the portal vein and hepatic artery can also be disrupted by hepatic disease or volatile anesthetic agents. Halothane and enflurane decrease both portal venous and hepatic arterial flow as a result of systemic vasodilatation and a slightly negative inotropic effect [216–219]. Isoflurane, desflurane, and sevoflurane increase hepatic artery flow but decrease portal venous flow [220], making them the preferred anesthetic agents in patients with liver disease [221]. Isoflurane, desflurane, and sevoflurane undergo less hepatic metabolism (0.2% of isoflurane) than either halothane (20%) or enflurane (2–4%) and have a lower risk of drug-induced hepatitis [216,222,223]. Halothane hepatitis may involve immune sensitization to trifluoroacetylated proteins formed by CYP2E1 metabolism of halothane in genetically predisposed individuals [222]. Its metabolism can be inhibited by prior administration of disulfiram.

The actions of neuromuscular blocking agents (e.g., mivacurium) may be prolonged in patients with liver disease because of reduced plasma pseudocholinesterase activity, decreased biliary excretion, and an increase in the volume of distribution [224]. Atracurium and cisatracurium are metabolized independent of the liver, making them the preferred agents in patients with liver disease or biliary obstruction [221]. The long-acting doxacurium can be used for prolonged surgical procedures including LT [225]. Other neuromuscular blocking agents such as vecuronium and rocuronium are degraded by the hepatic system exclusively [226].

Because of reduced hepatic blood flow, the metabolism of morphine, meperidine, and oxycodone may be decreased in patients with liver disease and portal hypertension, resulting in a prolonged half-life and increased bioavailability; in contrast, fentanyl, sufentanyl, and remifentanyl clearance is unaffected and these are the preferred narcotic agents [227]. If the use of longer-acting opioids is desired, lower doses at less frequent intervals should be administered in cirrhotic patients.

Slower metabolism of benzodiazepines such as diazepam, midazolam, and chlor-diazepoxide can lead to accumulation and prolonged clinical effects. Hence, oxanepam and lorazepam, which are eliminated by glucuronidation without hepatic metabolism, are preferred [228].

Barbiturates, which do not affect hepatic blood flow significantly, bind to γ -aminobutyric acid receptors in the brain and can precipitate hepatic encephalopathy. They should be used with caution in patients with liver disease. Although the metabolism of thiopental is decreased in patients with cirrhosis, plasma protein binding of thiopental is also decreased, so that total body clearance of the drug is unaltered in cirrhosis [229]. Although drug elimination is largely unchanged after a single induction dose of intravenous sodium thiopental or propofol, multiple doses or a continuous infusion may lead to prolonged clinical effects [230].

9.5 LIVER SURGERY AND REGENERATION

The human liver has the unique ability to regenerate after injury, restoring its original mass and function. Hepatic resection is safely accomplished for malignant and benign diseases because of this unique ability. Regeneration is a highly regulated process involving intra- and extrahepatic cellular signals and pathways. Animal studies show that cytokines responsible for hepatic regeneration include hepatocyte growth factor, transforming growth factor (TGF) α , insulin, and glucagon [231–238]. Hepatocellular

regeneration is influenced by age. Older livers show delayed and slower regeneration after acute injury than younger livers. In steatosis, abnormalities in induction of cytochrome P450 play a role in the pathophysiology of mitochondrial damage and may contribute to poor liver regeneration [239–241].

Follow up of adult living liver donors shows that a large amount of regeneration occurs in the first one to two weeks after resection for donation, but most remnant livers do not return to original size even after a year [242,243]. Numerous influences may interfere with the balance between maintaining differentiated hepatocyte function and cellular replication for survival [244]. After hepatic resection or transplantation, hepatocytes recover and regenerate at the expense of normal hepatic metabolism. The success of restoring lost liver mass and repairing tissue injury determines the ability of the liver to recover and support normal metabolic function. An inability to maintain this process after injury or liver resection may lead to hepatic decompensation, liver failure, and “small-for-size” syndrome [245].

9.6 LIVER TRANSPLANTATION AND DRUG METABOLISM

LT is the only curative option in patients with severe hepatic dysfunction or hepatic failure. It is also a means of cure for some liver tumors, most commonly hepatocellular carcinoma. In children, it is performed primarily for biliary atresia and inborn errors of metabolism.

The first step in LT is harvesting or procurement of the donor organ. Following this, the graft is preserved in solution until the time of implantation in the recipient. Preservative solutions can now extend this preservation period for close to 24 h, and this has changed procurement practices and the availability of organs for the better. The recipient operation involves the removal of the recipient liver (resulting in the anhepatic phase) and then graft implantation, which requires revascularization and biliary reconstruction.

Regeneration is crucial in LT. In cadaveric whole graft LT, ischemia-perfusion injury occurs during graft preservation. Regeneration occurs immediately after transplant, according to the extent of preservation injury [246,247]. Similarly, hepatic regeneration is important in transplanting a small graft into a larger recipient, as is the case in adult-to-adult live donor transplantation [248].

LT also involves removal of the gallbladder with a consequential disruption of bile flow. In cases where a temporary T-tube is required to drain the bile duct for a longer period, the absorption of fat-soluble drugs may be further affected.

9.6.1 Graft Versus Recipient Size

Advancement in surgical techniques has enabled living donor LT to increase the availability of liver grafts available in the organ donor pool. In pediatric LT, deceased donor size-matched allografts are rarely available. To overcome this, reduced size LT where the donor liver is surgically reduced in size to meet the needs of the pediatric recipient is used in split-LT. With this technique, a potential deceased donor graft benefits two potential recipients [249]. Similarly, in pediatric living-related donor operations, the left lobe of the liver, or a portion of it, is taken as the donor graft

from the parent [250]. The same is applied in adult-to-adult live donor transplantation, in which the right hepatic lobe is used as the donor graft, unless the size of the donor's left hepatic lobe per se suffices. In general, a donor liver allograft has to be within 20% of the recipient's size. A large-for-size graft can impair breathing or closure of the abdomen, whereas a small-for-size graft may be inadequate for survival. The amount of liver graft implanted is important in post-LT regeneration. The safety limits of selecting graft size/volume in living donors vary from 30–50% of “standard liver volume” to 0.8–1.0% of recipient body weight [251–255]. Small-for-size grafts [256] (graft weight/standard liver volume ratio <40% or graft-to-recipient weight ratio <0.8%) are associated with poor survival and prolonged hyperbilirubinemia [251,257]. Although small grafts can regenerate, there is significant functional impairment of the grafts resulting in prolonged cholestasis and histology consistent with ischemic injury. This functional impairment may interfere with drug pharmacokinetics. Other clinical features of this syndrome include delayed protein synthesis and increased surgical complications, massive ascites, gastrointestinal bleeding, increased infection, and renal dysfunction [251,255,258].

Studies have shown that adult-to-adult live donor transplant recipients require lower doses of immunosuppression in the early postoperative period than patients receiving whole grafts [259], even if the graft received is of adequate weight for the recipient.

9.6.2 Drug Metabolism in the Post-LT Patient

The post-liver transplant patient often has fluid, electrolyte, and nutritional abnormalities, as well as biliary tract dysfunction. These multiple physiologic changes can result in pharmacokinetic alterations of drugs administered in the post-LT setting [260].

9.6.2.1 Absorption. Post-LT, the absorption of lipophilic drugs may be dramatically improved. This has been demonstrated for the absorption of lipid-soluble drugs (e.g., cyclosporine A) and lipid-soluble vitamins (e.g., vitamin A, vitamin E), which improves after successful LT and reestablishment of bile flow and normal excretion of bile salts. In children, vitamin E deficiency and its neurologic complications in liver failure patients are reversed after LT.

9.6.2.2 Protein Binding. Drug's protein binding is affected by the synthetic capacity of the liver and the pathophysiologic changes associated post-LT.

The serum concentration of albumin in liver transplant recipients remains low for months following surgery. This results in a lower protein-bound fraction for drugs, which are albumin bound. However, when compared to patients with chronic liver disease, the protein binding of diazepam and salicylic acid is greater in post-liver transplant patients because of the removal of endogenous binding inhibitors.

Conversely, the concentration of α_1 -acid glycoprotein increases post-LT and remains elevated beyond a month. Accordingly, drugs that bind to this protein will have lower free concentrations. The unbound fraction of lidocaine in the plasma of post-liver transplant patients is lower than that in normal volunteers.

9.6.2.3 Hepatic Clearance. Drug metabolism in the post-liver transplant patient may be altered by a multitude of factors, including preservation injury, initial decreased

hepatic blood flow, and induction or inhibition of microsomal enzymes by immunosuppressant agents or other commonly used drugs in the post-LT period. Physiologic changes as a result of improved organ function include improved liver metabolism and improved bile salt and protein production, although the organ function is not considered to be entirely normal. In the early postoperative period, all the above changes may affect the pharmacokinetics of administered medications.

First-pass metabolism is also altered in the transition to normal hepatic function. Altered biliary function affects the absorption of lipophilic compounds and the elimination of drugs and their metabolites as well. For example, biliary dysfunction in liver transplant patients results in a high concentration of cyclosporine metabolites in the blood.

Generally, cytochrome P450 activity is depressed in the early posttransplantation period and recovers over the first few months. Hepatic mRNA gene expression for CYP3A4, 3A5, 2E1, and 1A2 increase significantly over time from LT [261]. However, studies in liver transplant recipients have shown that CYP2E1 has enhanced activity in the first month [262], while CYP2D6 appears to be unaffected by the procedure [263,264]. Drugs that are substrates for CYP2E1 may require a dosage adjustment during this early period. Recipient age does not appear to influence the changes in major CYP450 enzyme capacity following LT. Donor gene polymorphisms of CYP450 may be more important in alterations of drug metabolism than recipient polymorphisms [265]. In the late LT period, stable liver transplant patients have demonstrated, by antipyrine kinetics, similar hepatic oxidative metabolizing capacity as compared to normal subjects.

Phase II metabolism has not demonstrated alterations with LT. Although sulfation and glucuronidation of acetaminophen is minimally altered in post-liver transplant patients, renal elimination of the conjugates/metabolites is impaired [266,267]. For numerous reasons, renal clearance of drugs in liver transplant patients is usually impaired in the immediate and early postoperative period.

9.6.3 Commonly Used Immunosuppressants in LT

The standard immunosuppression regime after LT is composed of corticosteroids plus a calcineurin inhibitor (tacrolimus (TAC) or cyclosporine A). An antiproliferative agent may be added for patients at higher risk of rejection. More recent studies have also used various agents (e.g., IL-2 receptor monoclonal antibodies) either as steroid-sparing agents or to delay the use of calcineurin inhibitors until renal function recovers (Table 9.4).

Most immunosuppressants have narrow therapeutic windows and are extensively metabolized by the liver. Fluctuating hepatic function from hepatic regeneration and the need for polypharmacy, especially in the early postoperative period, puts the patient at increased risk of drug–drug interactions or adverse drug reactions. In the period of hepatic regeneration, immunosuppressive drugs require intensive drug monitoring, in view of their narrow therapeutic window, adverse reactions, drug–drug interactions, and changing pharmacokinetics.

9.6.3.1 Steroids. Prednisone is well absorbed orally and has a long half-life, allowing for once daily dosing. It is converted to active prednisolone in the body and has multiple suppressive effects on the immune system. Barbiturates, phenytoin, and

TABLE 9.4 Immunosuppressants Used in Liver Transplantation

Steroids
• Methylprednisolone
• Prednisolone
• Prednisone
Immunophilin-binding agents
• Tacrolimus (Prograf®)
• Cyclosporine (Sandimmune®, Neoral®)
• Sirolimus (Rapamune®)
Antiproliferative agents
• Mycophenolate mofetil (CellCept®, Myfortic®)
• Azathioprine (Imuran®)
Anti-T-cell antibodies
• Muromonab-CD3 monoclonal antibody (OKT3)
• ALG/ATG globulin (Atgam® or Thymoglobulin®)
Interleukin-2 receptor monoclonal antibodies
• Daclizumab (Zenapax®)
• Basiliximab (Simulect®)

rifampicin decrease the effectiveness of prednisone, whereas prednisone will decrease the effectiveness of vaccines and toxoids.

The steroid dose varies from center to center but is highest during the anhepatic phase and immediately after LT, with a variable period of dose taper. Administration of high dose IV methylprednisolone or high dose oral prednisone (200 mg) is the first-line therapy for the treatment of acute graft rejection.

Common adverse effects of steroids include increased appetite, insomnia, and mood changes. Side effects seen with high doses or prolonged therapy include cataracts, hyperglycemia, hypertension, hirsutism, acne, sodium and water retention, and growth suppression.

9.6.3.2 Immunophilin-Binding Agents

9.6.3.2.1 Tacrolimus. TAC (Prograf®) binds to the cytoplasmic immunophilin, FK binding protein (FKBP-12), with subsequent inhibition of the activity of calcineurin. Calcineurin is an enzyme that stimulates cytokine production (e.g., IL-2) by activated T cells.

Oral TAC has incomplete and variable absorption resulting in poor bioavailability in liver transplant patients (~29% bioavailable). This requires the use of higher oral than intravenous doses to obtain similar blood concentrations. TAC decomposes in alkaline media, and medications that increase the pH of the gastrointestinal tract (e.g., antacids) will further decrease its oral absorption. Such drugs' administration should be spaced 2 h apart from TAC administration. TAC is 99% protein bound (mainly to albumin or α_1 -acid glycoprotein).

TAC is mainly metabolized by CYP3A4 to eight other metabolites, some of which are active. Expectedly, other drugs or pathophysiological processes affecting CYP3A4 activity can alter TAC concentrations. Macrolide antibiotics (e.g., erythromycin) and antifungal medications (e.g., itraconazole, fluconazole) can increase TAC levels, whereas anticonvulsants (e.g., phenytoin, phenobarbital) and rifampin can lower TAC

levels. Patients with hepatic dysfunction may require a reduction in dose. Less than 2% of the drug is excreted unchanged in the urine. At times, such drug interactions are taken advantage of clinically. For example, in patients who cannot afford the cost of TAC or who may have genetic polymorphisms that result in rapid TAC metabolism, enzyme inhibitors such as verapamil may be used to allow for a lower dosing of TAC while achieving therapeutic levels of TAC. The same principle is true for cyclosporine A as well.

The main adverse effects of TAC are neurologic. These range from mild effects such as insomnia, tremors, headaches, nightmares, and hyperesthesia to major effects such as seizures, confusion, psychosis, and coma, which may necessitate a withdrawal of the drug. TAC is nephrotoxic, and caution should be exercised with the concurrent use of other nephrotoxic drugs.

Intravenous TAC is dosed at 0.03–0.05 mg/kg/day by continuous infusion in the initial postoperative period. Oral TAC is dosed at 0.1 to 0.15 mg/kg/day as two divided doses. Dose is then adjusted according to trough blood levels and clinical findings. Pediatric patients clear the drug more rapidly and require two to four times higher doses than adults to maintain equivalent therapeutic considerations

9.6.3.2.2 Cyclosporine. Cyclosporine binds to the cytoplasmic immunophilin cyclophilin, which also blocks the action of calcineurin.

Cyclosporine is highly lipophilic and is dependent on bile for intestinal absorption. Following oral administration, the absorption of cyclosporine is incomplete (~30%) and erratic, especially in liver recipients with T-tube diversion of bile. The absorption of cyclosporine can be enhanced by a moderate fatty meal, so the patient should be advised to take cyclosporine with meals. Cyclosporine is available as standard formulation (Sandimmune®) or as a microemulsion (Neoral®). The microemulsion formulation has better and more reliable oral absorption, as it is less dependent on bile for its absorption. In a study of liver recipients with T-tube diversion, the bioavailability of the microemulsion was 6.5 times greater than that of the standard formulation [268]. Hence, the two formulations are not bioequivalent and cannot be used interchangeably. Pharmacologically, the microemulsion formulation has also been associated with a lower incidence of rejection compared to standard formulation [269]. Once absorbed, cyclosporine is highly protein bound (>90% to lipoproteins).

Cyclosporine is also mainly metabolized by CYP3A4 and shares the same drug interactions as TAC. Inhibitors of CYP3A will reduce the metabolism of cyclosporine and increase its blood concentrations. Substances that induce CYP3A activity will decrease its metabolism and elimination, decreasing its blood concentration and resulting in subtherapeutic levels with a risk of graft rejection. For example, grapefruit juice (enzyme inhibitor) decreases the metabolism of cyclosporine, while St John's Wort (enzyme inducer) increases its metabolism. More drug interactions have been reported with cyclosporine, although this may be a consequence of greater and longer experience with cyclosporine use. All the metabolites of cyclosporine A have less biological activity or toxicity than the parent compound. Dosage adjustments for cyclosporine are required in hepatic dysfunction.

Adverse reactions to cyclosporine include hypertension, nephrotoxicity, gingival hypertrophy, hirsutism, and tremor. Less common side effects may occur including seizures, headache, psychosis, paresthesias, and pancreatitis. Cyclosporine is also nephrotoxic. Caution should be exercised in using other nephrotoxic drugs concurrently.

The adult dose for intravenous cyclosporine is 2–5 mg/kg/day as a continuous intravenous infusion. Initial oral dose is 15 mg/kg/day and is tapered to a long-term dose of 5 mg/kg/day divided into one or two doses per day. As with TAC, children require higher doses of cyclosporine to maintain therapeutic drug concentrations. In large part, cyclosporine has been supplanted by TAC as the primary immunosuppressive agent post LT.

9.6.3.2.3 Sirolimus. The sirolimus–immunophilin complex binds to the mammalian target of rapamycin (mTOR), which inhibits the signal necessary for IL-2-induced T-cell proliferation [270].

Sirolimus is a lipophilic drug with poor oral bioavailability and extensive tissue distribution [271]. Sirolimus is predominantly metabolized by CYP3A4, and coadministration of enzyme inducers or inhibitors will affect the rate and extent of its metabolism. Examples of these are detailed above, as with TAC and cyclosporine.

Early studies showed that sirolimus was both effective when used in combination with cyclosporine in a steroid-sparing protocol [272], or in combination with prednisone and low dose TAC, which resulted in less TAC-associated nephrotoxicity [273]. However, recent findings have now prompted the US boxed warning that sirolimus is not recommended for use in de novo LT patients due to increased risk of hepatic artery thrombosis, graft failure, and the increased mortality risk when used in combination with TAC and/or cyclosporine.

9.6.3.3 Antiproliferative Agents

9.6.3.3.1 Mycophenolate Mofetil. Mycophenolate mofetil has a cytostatic effect on both the B and T lymphocytes.

Oral mycophenolate mofetil is available in a standard form (CellCept®) or as a delayed-release preparation (Myfortic®). Both forms should not be used interchangeably due to their differences in absorption. Antacids decrease the absorption of mycophenolate mofetil, and administration of the two drugs should be separated by at least 2 h. Food delays the absorption of mycophenolate mofetil, and when possible, the drug should be taken on an empty stomach. However, in some cases, mycophenolate mofetil is taken with food to minimize adverse gastrointestinal effects. After oral absorption, mycophenolate mofetil is hydrolyzed by the liver and gastrointestinal tract to the active metabolite, mycophenolic acid. Mycophenolic acid is conjugated with glucuronide to form an inactive compound. However, this metabolite may be converted back to the active parent drug in the blood. Mycophenolic acid enters the enterohepatic recirculation. The drug is highly albumin bound (97%). Total plasma concentrations will vary as protein synthetic capacity of the liver increases with recovery of the liver. Patients should be monitored closely when inhibitors or inducers of CYP3A4 are used. Plasma concentration monitoring has been suggested for mycophenolate mofetil, but a good correlation with efficacy and adverse effects has not been demonstrated.

Adverse effects with mycophenolate mofetil include gastrointestinal disturbances (nausea, vomiting, diarrhea), pure red cell aplasia, neutropenia, thrombocytopenia, headache, weakness, dizziness, and insomnia. Drugs with adverse effects similar to immunosuppressive agents, such as nephrotoxic drugs, should be used cautiously.

In adults, mycophenolate mofetil is dosed 1.5 g twice daily. In children, it is dosed at 40 mg/kg/day, in two divided doses.

9.6.3.3.2 Azathioprine. Azathioprine is an antiproliferative agent against both the B and T lymphocytes. It is metabolized to its active metabolites mercaptopurine, 6-thionosinic acid, and 6-thioguanine. Azathioprine is commonly used to treat autoimmune hepatitis. It can be used in LT to prevent graft rejection, but not as a treatment for established rejection. It is recommended that its dose be reduced by at least two-thirds during concurrent therapy with xanthine oxidase inhibitor allopurinol and that both drugs are not used together unless absolutely necessary. Xanthine oxidase converts the active metabolite of azathioprine into an inactive compound. Hence, drug interactions have been reported to cause significant drug toxicity, including fatalities [274–278].

9.7 THE USE OF HERBAL PREPARATIONS IN PATIENTS WITH LIVER DISEASE

Herbal medicine and its potential drug interactions are particularly challenging for the hepatologist. Although herbal medications are exempted from premarketing safety standards, many herb–drug interactions are known to occur. Surveys have demonstrated that up to 65% of patients with liver disease take some form of herbal preparation [279–282]. Herbal therapy usually consists of a mixture of ingredients, rather than a single pharmacologic agent. Plants can also vary based on the geographic location of their growth and the time of the harvest [283]. Preparations often contain constituents that can compete with the action of the principal agent. Botanical misidentification, product contamination or adulteration, mislabeling and variability in the collection and extraction processes adopted, and lack of active compound stability may all have an effect on purity of the final product. For example, an aqueous extract will not contain the same amount of an herb as an alcohol extract, or as the grounded leaves of the herb without extraction. Many herbs and plants may also be marketed under different names. For example, Echinacea is also known as *cone flower*, *black Samson*, *black susan*, *comb flower*, *scurvyroot*, *hedgehog*, *Missouri snakeroot*, and *Indian head* [284]. It is also challenging for the hepatologist to demonstrate hepatotoxicity or drug–herb interactions because patients usually omit mentioning their use, even upon direct questioning, because of their perceived safety [285].

Induction of cytochrome P450 enzymes by other drugs or alcohol may increase the production of toxic metabolites that mediate liver injury. For example, pyrrolizidine alkaloids and diterpenoid constituents of *Scutellaria* (found in skullcap, germander, and other *Teucrium* spp.) are well-known hepatotoxins metabolized via CYP3A4, and pharmacologic induction of CYP3A4 has been associated with increased toxicity from these herbal agents [286–289]. Pennyroyal, used as a general herbal tonic, is metabolized via CYP2E1 to the toxic metabolites pulegone and methofuran. Chronic alcohol ingestion that induces CYP2E1 activity may increase the risk of hepatotoxicity from this herb [283].

Conversely, herbs may also have a direct effect on the induction or inhibition of CYP450 enzymes, affecting their metabolism of other drugs (Table 9.5). Transplant

TABLE 9.5 Common Drug–Herb Interactions in Liver Disease

Herb	Interacting Medication
Danshen (<i>Salvia miltiorrhiza</i>)	Corticosteroids
Devil’s claw (<i>Harpagophytum procumbens</i>)	Anticoagulants, aspirin
Dong quai (<i>Angelica sinensis</i>)	Corticosteroids
Grapefruit juice	Cyclosporine, calcium channel blockers
Glycyrrhizin (licorice root)	Prednisolone, spironolactone
St John’s wort (<i>Hypericum perforatum</i> , goatweed)	Cyclosporin, indinavir, other protease inhibitors
Garlic, ginger, papaya extract, or tamarind (<i>Tamarindus indica</i>)	Aspirin, anticoagulants

recipients require immunosuppressants and other drugs that may have narrow therapeutic indices. St John’s Wort (*Hypericum perforatum*) is a widely used herbal product with many reported drug–herb interactions. The herb is known to induce CYP3A4 and P-glycoprotein expression. The results of a systemic review indicate that St John’s Wort lowers the blood concentration of multiple drugs, including cyclosporine, digoxin, warfarin, and theophylline [290]. Graft rejection related to subtherapeutic levels of cyclosporine caused by St John’s Wort has been reported in transplant patients [291].

Herbal or alternative medicine hepatotoxicity superimposed on preexisting liver disease must always be considered, especially because many herbs are used as “liver remedies” in patients with viral hepatitis and other chronic liver diseases. Alternative medicine-induced liver injury, such as drug hepatotoxicity, can clinically and histologically mimic any type of liver disease [285].

9.8 CONCLUSIONS

In humans, the liver is a major site of drug metabolism. The multiple functions this organ is responsible for to maintain homeostasis is the reason why liver disease can sometimes result in several altered states in the body (e.g., coagulopathy, altered protein levels, altered fluid balance). Hence, any liver disease has the potential to alter drug disposition and metabolism. Dosing in patients with cirrhosis should be undertaken with caution, and the physician or pharmacist needs to be mindful that many common drugs may require dose adjustments while prescribing for such patients.

10.1 SUMMARY

This chapter explores the relation between drug biotransformation and pharmacological activity. More precisely, it surveys the formation of active metabolites and exemplifies cases of metabolites as or more active than the parent drug. Because very few drug conjugates are pharmacologically active, the focus is on metabolic reactions of functionalization (i.e., phase I), namely, oxidations, reductions, or hydrolyses.

The first section sets the scene by explaining the *pharmacokinetic/pharmacodynamic (PK/PD) interplay* that underlies drug action, and the existing continuum ranging from drugs devoid of active metabolites, to drugs yielding some active metabolite(s), to prodrugs whose activity is due solely to the metabolite. *Soft drugs* are briefly exemplified since they nicely illustrate the concept of drugs designed to be rapidly metabolized to inactive, atoxic metabolites.

The second section is dedicated to drugs whose activity depends in part on the presence of one or more active metabolite(s). Thus, the drug's action can be prolonged, as exemplified with *diazepam* and some other benzodiazepines. Alternatively, a drug's

pharmacological spectrum can be broadened by a metabolite; witness the antinociceptive activity of *codeine*, which is essentially due to its metabolite morphine. In another scenario, both the drug and its metabolite contribute comparatively to the clinical effect (e.g., *tramadol*). Finally, a drug such as *tamoxifen* is metabolized to one or more highly active metabolite(s).

The third section covers carrier-linked prodrugs, the examples presented therein having been selected to illustrate significant objectives in prodrug design. Thus, *fospropofol* was developed with the aim of overcoming a pharmaceutical hurdle, namely the low solubility of propofol. The lack of oral absorption of the anti-influenza agent Ro-64-0802 was overcome using simple physicochemical principles, namely, by masking its highly hydrophilic carboxylate group with a bioreversible ester function to yield *oseltamivir*. Another strategy to improve oral absorption is by targeting intestinal transporters, as illustrated with *valacyclovir*. The last example, *capecitabine*, exemplifies a more ambitious objective, namely, tissue targeting via organ-selective activation.

The fourth section deals with another class of prodrugs known as *bioprecursors*. Here, metabolic activation is by redox modification of a functional group, without cleavage of a promoiety. Four examples are presented, namely, *nabumetone*, a long-acting non-steroidal anti-inflammatory (NSAI) prodrug with low gastric toxicity, the two anti-aggregating agents *clopidogrel* and *prasugrel*, whose bioactivation unmasks a highly reactive sulfenic acid group, and *tirapazamine*, an antitumor bioprecursor activated by reduction to a DNA-damaging radical. Clopidogrel is treated in some detail to illustrate the influence of genetic factors on clinical outcomes.

The fifth section briefly illustrates drug–drug interactions (DDIs) at the metabolic level, taking the antiretroviral protease inhibitors (PIs) as a case in point. A concluding section then completes the chapter.

10.2 BACKGROUND

To open this chapter, we note that the continuously increasing significance of drug metabolism investigations in drug discovery and development cannot be fortuitous [1–9]. The pharmacological and toxicological consequences of drug metabolism account for this phenomenon, which simultaneously drives, and is driven by, the many methodological, factual, and conceptual advances in this discipline. In a perspective of drug discovery, a number of metabolites of established drugs were found to have comparable or improved therapeutic properties compared to their parent and have become useful drugs in their own right. In addition to the examples discussed in the text, one can single out desloratadine (from loratadine), cetirizine (from hydroxyzine), fexofenadine (from terfenadine), and oxazepam (from diazepam). Even more significant is the discovery of paracetamol, which has replaced phenacetin, its more toxic parent. As a result, the pharmacological activity of metabolites even plays a role in bioequivalence studies [10].

10.2.1 The PK–PD interplay

Basically, there are two types of interactions between bioactive compounds and biological systems [6,11]. A drug acting on a biological system elicits a pharmacological and/or a toxic response, in other words a *pharmacodynamic (PD) event*. In the present

context, we discriminate between pharmacological activities (in effect, wanted and/or favorable PD effects) and toxic effects (in fact, all adverse effects a drug or chemical can elicit). In concert with PD events, the biological system “acts” on the xenobiotic by absorbing, distributing, metabolizing, and excreting it. These are the *pharmacokinetic (PK) events*. Most of these processes are mediated by enzymes or transporters and are active in the sense that they consume energy produced by the biosystem; others in contrast are passive.

Significantly, there is a mutual interdependence between PD and PK events, since it is well known that PK events such as metabolic activation or inactivation influence PD responses. This is the main focus of this chapter. Symmetrically, the PK behavior of a xenobiotic can be markedly influenced by the overexpression of metabolizing enzymes (a typical PD response) as mediated by substrates or other xenobiotics binding to nuclear receptors [12,13]. Such a situation is exemplified in Section 10.6.

10.2.2 Drugs, Metabolites, and Bioactivities—A Continuum

An important information in any drug’s dossier is the activity (or lack thereof) of its metabolites. What should be realized, however, is that “activity” is usually understood to imply the same pharmacological target as the parent molecule [1], an implicit meaning we also adopt. Here, we outline the various combinations of activities to be illustrated, (i) from intrinsically active drugs having no active metabolite to (ii) intrinsically active drugs having one or more active metabolites to (iii) intrinsically inactive “drugs” (i.e., prodrugs), whose therapeutic effects necessitate metabolism to an active metabolite (i.e., bioactivation). For example, sedative-hypnotic benzodiazepines fall in two categories [14]. Some have no active metabolite, for example, the 3-hydroxylated benzodiazepines such as lorazepam, oxazepam, and temazepam, which undergo O-glucuronidation and cleavage reactions. Other intrinsically active benzodiazepines such as diazepam have one or more active metabolite(s), sometimes long-acting ones. In a quantitative perspective, some drugs have a metabolite of comparable activity (e.g., tramadol), while some others have one or more highly active ones (e.g., tamoxifen). The extreme case of prodrugs will be treated separately.

10.2.3 Bioactivation and Metabolic Conjugation

This chapter is dedicated to drug activation by phase I reactions. As a reminder, these imply the creation or modification of a functional group in a substrate molecule by reactions of oxidation or reduction (redox reactions catalyzed by oxidoreductases, EC 1) or reactions of hydrolysis catalyzed by hydrolases (EC 3) [4,5,15].

The reason for not including phase II reactions (i.e., conjugation reactions catalyzed mainly by transferases EC 2) is that only a very small number of drug conjugates are pharmacologically active (i.e., having a wanted and/or favorable PD effect). A frequently cited example is that of *morphine*, which is conjugated on its phenolic and secondary alcohol groups to form the 3-*O*-glucuronide (a weak opiate antagonist) and the 6-*O*-glucuronide (a strong opiate agonist), respectively [16].

An intriguing and very rare reaction of conjugation occurs for *minoxidil*, an hypotensive agent that also stimulates hair growth. This drug is an *N*-oxide, and the actual active form responsible for the different therapeutic effects is the stable *N*-*O*-sulfate ester [17].

Figure 10.1 Examples of soft drugs, namely, the curarimimetic succinylcholine (1), which is hydrolyzed to choline (2) and succinic acid (3), and the β -blocker esmolol (4), whose metabolite is inactive due to the unmasking of a hydrophilic carboxylate group.

10.2.4 Drugs Having No Active Metabolite

An example of drugs designed to have neither active nor toxic metabolites is that of *soft drugs*, a concept pioneered and extensively developed by Bodor and Buchwald [18]. In practical terms, soft drugs (i) are bioisosteres of known drugs, (ii) contain a labile bridge (often an ester group), and (iii) are cleaved to metabolites known to lack activity and toxicity. In other words, soft drugs bear a close stereoelectronic analogy with the target drugs, but a rapid breakdown to inactive metabolites is programmed into their chemical structure. A typical example of a soft drug is *succinylcholine* (1 in Fig. 10.1), although the discovery of this agent predates by decades the concept and term of soft drugs. In most individuals, this curarimimetic agent is very rapidly hydrolyzed to choline (2) and succinic acid (3) by plasma cholinesterase with a half-life of about 4 min [19,20].

Soft drugs may be found in a variety of therapeutic classes. Thus, a valuable class of soft β -blockers are aryloxypropanolamines, which possess an ester group in the para-position, as illustrated by the clinically useful *esmolol* (4) [21]. In this compound, as in others, the para-substituent has an intermediate polarity compatible with good receptor affinity, but hydrolysis to its metabolite 5 unmasks a carboxylate group, whose high polarity is incompatible with receptor affinity. The *in vitro* half-life of esmolol in whole blood was about 2, 13, and 23–27 min in rats, dogs, and humans, respectively. In patients, recovery from β -blockade began 2 min after discontinuation of infusion and was complete at about 18 min.

Paracetamol (6 in Fig. 10.2; also known as *acetaminophen*) is another example of a drug having no active metabolite, but we mention it here to highlight how unexpected findings remain possible even with highly popular drugs. Recently indeed, evidence has begun to challenge the general belief by suggesting that part of the clinical effect of paracetamol might in fact be contributed by an unusual metabolite [22]. One of the pain pathways and its inhibition involve vanilloid receptors, including the capsaicin receptor (transient receptor potential cation channel, subfamily V, member 1; TRPV1). This receptor shows a marked affinity for metabolites of arachidonic acid (the so-called endovanilloids), the best known of which is anandamide. Intriguingly,

Figure 10.2 Paracetamol (**6**) and its recently discovered metabolite *N*-arachidonoyl-4-hydroxyaniline (**7**).

N-arachidonoyl-4-hydroxyaniline (**7**), a known metabolite of paracetamol and an analog of anandamide, was shown to have a potent inhibitory effect on TRPV1. However, the clinical contribution of this metabolite in patients administered paracetamol remains to be understood.

10.3 DRUGS WITH ACTIVE METABOLITES

Drugs having both intrinsic activity and active metabolite(s) may be more numerous than generally believed, but information is not always available. In this section, we examine a number of cases chosen for the different perspectives they allow on this aspect of pharmacotherapy.

10.3.1 Benzodiazepines, Drugs With or Without Active Metabolites

As mentioned above, benzodiazepine drugs can be classified into two groups, those having one or more active metabolite(s) and those having none. Criteria of half-life and duration of action allow further discrimination among these drugs [23–27]. Thus, *midazolam* and *triazolam* both have a short half-life in humans, as have their active metabolites *1*-hydroxymidazolam and *1*-hydroxytriazolam, respectively. As a result, these two drugs have a short duration of action, which makes them good short-acting hypnotics.

Benzodiazepines of longer duration of action are useful as sedatives or antiepileptics. Three examples are shown here, each of which has a different story to tell. *Clorazepate* is unusual among benzodiazepines due to the presence of its carboxylate group. Its metabolism is by decarboxylation to the long-acting *desmethyldiazepam*, followed by 3-hydroxylation to *oxazepam*. The drug does have affinity for the benzodiazepine receptor [26], but it appears incapable of crossing the blood–brain barrier and is rapidly metabolized to these two active metabolites [28]. In other words, it is a prodrug not because of lack of target affinity but for its incapacity to reach the target organ. *Diazepam* is also a sedative with a long, biphasic half-life, but one that acts both directly and via its three active metabolites, *desmethyldiazepam*, 3-hydroxydiazepam (*temazepam*), and *oxazepam*. *Flurazepam* is marketed mainly as a hypnotic, and indeed, its half-life is very short, the drug having disappeared from plasma 3 h after an oral dose to human volunteers [29]. An active metabolite is *N*¹-(2-hydroxyethyl)flurazepam, which is eliminated within a few hours. However, its *N*(1)-dealkylation produces *desalkylflurazepam*, a close analogue of *desmethyldiazepam* with an even longer half-life. As a result, flurazepam is unsuitable as a hypnotic in individuals who produce high levels of *desalkylflurazepam*.

Figure 10.3 Codeine (**8**) and its active metabolite (**9**) produced by a CYP2D6-catalyzed reaction of O-demethylation.

10.3.2 Codeine, a Drug With a Differently Acting Metabolite

There are two main reasons why *codeine* (**8** in Fig. 10.3) is of significance in our context. First because the production of *morphine* (**9**), its active metabolite, is under strong genetic control [30]. And second, because there is a qualitative difference in the activity of drug and metabolite, in contrast with many known cases of active metabolites.

While codeine *per se* is an antitussive agent, it is often prescribed as an analgesic of medium strength. About two decades ago, reports began to appear on the lack of analgesic response in some patients administered codeine [31]. This fact was correlated with barely detectable plasma levels of morphine in some patients subsequently phenotyped as “poor metabolizers,” an obsolete terminology to describe individuals lacking a given drug-metabolizing activity. The culprit enzyme, in this case, is cytochrome P450 2D6 (CYP2D6), the affected patients (ca. 5–8% of the population) having nonfunctional *CYP2D6* alleles [12].

The story does not end here, however, since there is now recent evidence that a few individuals suffered from morphine intoxication following codeine intake [32–34]. The postoperative death of a healthy two-year-old boy was also traced to morphine intoxication following normal dosage of codeine [35]. The cause of overproduction of morphine in these patients is also genetic, in this case, gene duplication or multiplication resulting in three or more functional *CYP2D6* alleles.

10.3.3 Tramadol, a Drug With a Metabolite of Comparable Activity

Tramadol (**10** in Fig. 10.4) is a frequently used centrally acting analgesic characterized by a high efficacy, low potential for dependence or abuse, and low level of side effects (no relevant respiratory depression or effects on blood pressure and heart rate) [36–39]. This drug is particularly worthy of note for its dual mechanism of action, being both a weak opioid agonist and an inhibitor of monoamine neurotransmitter reuptake. For good reasons, the drug is used as the racemic mixture of two of its four stereoisomers, both its (–)-(1*S*,2*S*)- and (+)-(1*R*,2*R*)-enantiomers contributing synergistically to its *in vivo* activity.

In experimental pharmacology, (+)-tramadol proved a more active μ -receptor agonist than its (–)-enantiomer, and it also inhibited serotonin reuptake. In contrast, the (–)-enantiomer is an inhibitor of noradrenaline reuptake in addition to its weaker opioid effects. Furthermore, both enantiomers are metabolized by CYP2D6 to the corresponding *O*-desmethyltramadol enantiomers (**11**) with little or no substrate enantioselectivity. Both enantiomers of *O*-desmethyltramadol are more active than (+)-tramadol as μ -receptor agonists, but their blood–brain barrier permeation is lower. It is noteworthy

Figure 10.4 The two (active) enantiomers of *trans*-tramadol (**10**) and their even more active *O*-desmethyl metabolites.

that to the best of our knowledge, no effect on monoamine neurotransmitter reuptake has been reported for the metabolites. In clinical pharmacology, tramadol-induced analgesia is thus found to result from the combined and synergetic effects of four active entities. And while CYP2D6-deficient patients produce very little *O*-desmethyltramadol, tramadol activity is weaker but not absent in such patients [30,34].

10.3.4 Tamoxifen, a Drug Having Highly Active Metabolites

The complex and clinically highly relevant case of *tamoxifen* (**12** in Fig. 10.5) is summarized here. This estrogen receptor antagonist is extensively used for endocrine

Figure 10.5 Tamoxifen (**12**) and its highly active metabolites 4-hydroxytamoxifen (**13**) and *N*-desmethyl-4-hydroxytamoxifen (**15**; endoxifen).

treatment of breast cancer [40]. Its metabolism is quite complex and leads to at least 13 oxidative metabolites [41,42], not to mention conjugation reactions. A pharmacologically significant route is aromatic oxidation to the active *4-hydroxytamoxifen* (**13**). However, the most important metabolic pathway in qualitative and quantitative terms is N-demethylation to the secondary amine *N*-desmethyltamoxifen (**14**), a reaction catalyzed mainly by CYP3A4. This metabolite, while reaching high plasma levels, is not as active as 4-hydroxytamoxifen and the second-generation metabolite *N*-desmethyl-4-hydroxytamoxifen (**15**) known as *endoxifen*.

A number of investigations have demonstrated that 4-hydroxytamoxifen and endoxifen are equipotent and many times more active as antiestrogens than the parent drug [43,44]. When taking plasma levels in consideration, it seems that the main contributor to therapeutic activity in patients is endoxifen, and to a lesser extent tamoxifen and 4-hydroxytamoxifen [45–47]. This has led to concerns that genotypic differences in CYP2D6 and the coadministration of drugs inhibiting this enzyme may have an impact on clinical outcomes in women treated with tamoxifen [48].

10.4 CARRIER-LINKED PRODRUGS

10.4.1 Introduction

What makes prodrugs different from other drugs is the fact that they are devoid of intrinsic pharmacological activity, as clearly defined by Adrien Albert [49], who coined the term. As such, prodrugs are the opposite of soft drugs (see above). *Intentional prodrugs* are by far the most frequent ones in drug research and development and are obtained by rational derivatization or modification of a known active agent. A historically important example is that of the *fortuitous prodrug* *prontosil*, whose *in vivo* antibacterial properties were discovered in 1932 by Gerhard Domagk, winning him the 1939 Nobel Prize in Medicine [50]. But the prodrug nature of *prontosil* remained unknown until 1935, when the discovery of its active metabolite sulfanilamide was the milestone that led to the creation of all antibacterial sulfonamides [51].

The prodrug concept aims at helping medicinal chemists and pharmaceutical scientists to overcome a number of development problems unsolvable by analog design [52–56]. Overcoming such hurdles translates into a number of *objectives in prodrug design*. Pharmaceutical objectives imply solving serious formulation problems caused by poor solubility, insufficient chemical stability, or poor organoleptic properties. PK objectives are currently the most important ones in prodrug research. Foremost among these is a need to improve oral bioavailability by enhancing the oral absorption of the drug and/or decreasing its presystemic metabolism; other objectives are to improve parenteral absorption, to lengthen the duration of action of the drug by slow metabolic release, and finally to achieve organ/tissue-selective delivery.

PD objectives often imply decreasing systemic toxicity, including the masking of a reactive agent, the *in situ* activation of a cytotoxic agent, and more generally improving a drug's therapeutic index. As a note of caution, it should be clear from the onset that prodrug objectives are often strongly intertwined. As demonstrated by the examples below, the prodrug concept may be a valuable strategy to disentangle PK and PD optimization in the drug discovery phases.

This section deals with prodrugs composed of the drug molecule coupled to a promoiety (also known as a *carrier*). Here, bioactivation occurs by cleavage of the

Figure 10.6 Fospropofol (**16**), a water-soluble, marketed prodrug of the sedative-hypnotic drug propofol (**17**).

link between drug and carrier, in most cases due to hydrolysis. Section 10.5 considers redox-activated prodrugs (bioprecursors).

10.4.2 Fospropofol, a Product for Improved Solubility

Propofol (**17** in Fig. 10.6) is a sedative-hypnotic, whose mechanism of action is based on an allosteric modulation of GABA_A receptors, causing increased binding of γ -aminobutyric acid, its physiological ligand [57–59]. propofol provides sedation to patients undergoing uncomfortable interventions such as bronchoscopy or colonoscopy. It is also used for induction and maintenance of general anesthesia and in intensive care units for short or longer term sedation of medically ventilated adults.

Despite its advantages and extensive use, propofol suffers from a number of disadvantages such as pain at the injection site, a narrow therapeutic window, and a steep concentration–response curve bridging moderate sedation to general anesthesia. More relevant in the present context is its very low water solubility. As a result, propofol is administered intravenously as a lipid emulsion, which calls for absolute sterility. The lipid-based emulsions of propofol are fairly stable but tend to separate with the addition of other chemicals and changes in temperature or pH [59]. A most worrisome complication is propofol infusion syndrome, a rare but life-threatening event resulting from the long-term administration of high doses of the drug [60]. The syndrome is characterized by metabolic acidosis, acute renal failure, rhabdomyolysis, hyperlipidemia, and cardiac dysfunction.

The *pharmaceutical problems* associated with the poor solubility of propofol have provided a worthy justification to the development of water-soluble prodrugs. *Fospropofol* (**16**; propofol *O*-methyl phosphate disodium) has emerged as the lead candidate for a water-soluble prodrug of propofol and has recently been approved for monitored anesthesia in adults undergoing diagnostic or therapeutic procedures [61–63]. The prodrug is very stable toward chemical hydrolysis [64] and is very rapidly hydrolyzed by hepatic and endothelial alkaline phosphatases. The products of the reaction are propofol, formaldehyde (which is rapidly converted to formate), and phosphate.

Our understanding of the PK/PD relations of fospropofol underwent severe regression when it was found that the bioanalytical assay used in all PK/PD studies published up to 2009 was inadequate and yielded unreliable propofol plasma concentrations [65]. As a result, six papers were withdrawn [66], yet some unaware readers might continue to rely on conclusions found in previously published reviews.

19

10.4.3 Oseltamivir, a Prodrug for Oral Absorption

Achieving improved oral absorption and generally oral bioavailability is a frequent rationale in marketed prodrugs [67,68]. Inhibitors of angiotensin-converting enzyme (ACE) such as benazepril and enalapril offer much-reviewed examples [69,70]. Here, we focus on two neuraminidase inhibitors of value against type A and B influenza in humans [71–73]. Target-oriented rational design led to highly hydrophilic agents that are not absorbed orally. One drug in clinical use is *zanamivir*, a highly hydrophilic drug administered in aerosol form.

Another active agent is Ro-64-0802 (**19** in Fig. 10.7; now known as *oseltamivir carboxylate*), which also shows high *in vitro* inhibitory efficacy but practically no oral bioavailability due to its high polarity [74,75]. In contrast, its ethyl ester pro-drug *oseltamivir* (**18**) is well absorbed orally and undergoes rapid carboxylesterase 1 (CES1)-catalyzed hydrolysis *in vivo* to produce high and sustained plasma levels of the active agent [76–80]. In this example, the lack of oral absorption of the anti-influenza agent Ro-64-0802 was overcome with the help of a simple physicochemical principle, namely, the masking of a highly hydrophilic carboxylate group with a reversible ester function.

10.4.4 Valacyclovir, a Prodrug Targeting an Intestinal Transporter

Acyclovir (**21** in Fig. 10.8) is a nucleoside analogue used systemically and locally to treat herpes simplex virus (HSV-1 and -2) infections. It is also used in higher doses to treat infections from the varicella zoster virus (VZV). Acyclovir is a valuable drug, yet its oral absorption is modest (15–30%) [81]. This has led to many potential prodrugs being prepared and examined, with the (*S*)-valyl ester being selected and now marketed as *valacyclovir* (**20**) [82,83].

This prodrug is of particular interest as its intestinal absorption is an active one mediated by the di-/tripeptide transporter PEPT1 [84], the resulting bioavailability of the active agent being ~50–60%. This bioavailability is clearly less than expected, given the good affinity of valacyclovir for the transporter. And indeed stability studies have shown valacyclovir to undergo partial degradation in the upper lumen of the small intestine [85].

Practically, the totality of absorbed valacyclovir is activated to acyclovir by a serine hydrolase initially known as *biphenyl hydrolase-like protein* (BPHL). This enzyme, now characterized as human valacyclovirase, is specific for α -amino acid esters and

Figure 10.8 Acyclovir (**21**), a poorly absorbed antiherpes virus drug, and its (*S*)-valyl ester prodrug valacyclovir (**20**).

has been shown to hydrolyze the prodrugs of a broad range of antiviral and anticancer nucleoside analogs such as zidovudine and gemcitabine [86,87].

10.4.5 Capecitabine, a Prodrug for Targeted Delivery

The objective of organ- or tissue-selective delivery, also known as the search for the *magic bullet*, is receiving ever increasing interest in the tumor-selective delivery of anti-cancer agents. A clinically significant example is that of *capecitabine* (**22** in Fig. 10.9), a multistep, orally active prodrug of 5-fluorouracil (**25**; 5-FU) [82,88]. Capecitabine is well absorbed orally and undergoes three activation steps resulting in high tumor concentrations of the active drug. It is first hydrolyzed by liver carboxylesterase (CES), the resulting metabolite being a carbamic acid that spontaneously decarboxylates to 5'-deoxy-5-fluorocytidine (**23**). The enzyme cytidine deaminase (EC 3.5.4.5), which is present in the liver and tumors, then transforms 5'-deoxy-5-fluorocytidine into 5'-deoxy-5-fluorouridine (**24**). Transformation into 5-FU (**25**) is catalyzed by thymidine phosphorylase (EC 2.4.2.4) and occurs selectively in tumor cells [89–93].

Capecitabine was first approved for the cotreatment of refractory metastatic breast cancer. Its therapeutic spectrum now includes metastatic colorectal cancer, and there are hopes that it might broaden further as positive results of new clinical trials become available. Capecitabine thus affords an impressive gain in therapeutic benefit compared to 5-FU because of its oral bioavailability and a relatively selective activation in (and thus delivery to) tumors.

10.5 BIOPRECURSORS

In contrast to the more traditional, carrier-linked prodrugs, bioprecursors do not contain a promoiety (i.e., a carrier moiety) but are activated enzymatically either by reduction or by oxidation, hence, their alternative designation as *redox-activated prodrugs* [94]. The bioactivation reaction creates either a *pharmacophoric group* (e.g., nabumetone) or a *chemically reactive group* (e.g., clopidogrel and tirapazamine).

Figure 10.9 Capecitabine (22), a multistep, tumor-targeted prodrug of 5-fluorouracil (25).

Figure 10.10 The bioprecursor nabumetone (26) and its metabolite 6-methoxynaphthylacetic acid (27), a long-acting nonsteroidal anti-inflammatory agent.

10.5.1 Nabumetone, a Long-Acting NSAID Prodrug with Low Gastric Toxicity

A rather complex and intriguing example of bioprecursors is afforded by *nabumetone* (26 in Fig. 10.10). In humans and experimental animals, this prodrug undergoes three major initial metabolic pathways, namely, oxidative O-demethylation, carbonyl reduction, and a complex route likely involving oxidation of the terminal $-\text{CH}_3$ to $-\text{COOH}$, followed by coenzyme A conjugation and β -oxidation to 6-methoxynaphthylacetic acid (27; 6MNA) [95,96]. The latter route is the major one in humans, where it accounts for at least one-third to one-half of a dose. 6MNA is the active metabolite of nabumetone. It is characterized by a very long serum half-life in humans (about 24 h, range 17–74 h), because of a slow hepatic clearance and absence of renal clearance [97,98]. The anti-inflammatory and analgesic activities of 6MNA are explained by its inhibition of cyclooxygenase, with a modest selectivity toward cyclooxygenase-2 (COX-2) [99,100].

A valuable feature of this metabolite is its affinity for synovial fluids where it reaches substantial concentrations, making it useful in chronic inflammatory arthropathies.

One of the reasons why nabumetone is discussed here is its low gastric toxicity that sets this prodrug apart from other NSAIDs [101–103]. In numerous toxicological and clinical studies, nabumetone has indeed confirmed a high therapeutic index (ratio of toxic dose overtherapeutic dose). It now appears that this low gastrointestinal toxicity is due to two factors. First, the nonacidic nabumetone has limited affinity for the gastric mucosa, where its concentrations remain low; and not being able to inhibit cyclooxygenase, it cannot cause COX-related significant damages in the gastrointestinal (GI) tract. As for its active metabolite 6MNA, its presence was undetectable in rat gastric mucosa given nabumetone orally [104]. In addition, nabumetone itself has shown an intrinsic gastroprotective effect by inhibiting neutrophil functions. Specifically, neutrophils are agents in NSAID-induced lesions in the GI tract. Indeed, NSAIDs such as indometacin facilitate their infiltration in rat gastric mucosa and induce their respiratory burst. These effects were inhibited by nabumetone.

10.5.2 Clopidogrel and Prasugrel, the Masking of a Highly Reactive Metabolite

The masking of a reactive agent to improve its therapeutic index is aptly exemplified by the successful anti-aggregating agent *clopidogrel* (**28** in Fig. 10.11) [105–107]. This compound, whose molecular mechanism of action was poorly understood for years, is now known to be a prodrug. But while its major metabolic route in humans (about 80% of a dose) is indeed one of ester hydrolysis, this reaction leads to the inactive acid. Most of the remainder of a dose of clopidogrel is activated in a three-step sequence. First, cytochromes P450s (3A and 2C19) oxidize clopidogrel to *2-oxo-clopidogrel* (**29**). This is followed by a CYP-catalyzed sulfoxidation to the *cyclic sulfoxide intermediate* **30** [106]. The latter hydrolyzes spontaneously to a highly reactive *sulfenic acid metabolite* (**31**), which forms a covalent S–S bridge with a thiol group in platelet ADP receptors, thereby causing their long-lasting inactivation. Interestingly, the same activation mechanism appears to account for the potent and irreversible inhibition of human CYP2B6 by clopidogrel [108].

The sulfenic intermediate can also be reduced by glutathione, leading to the corresponding thiol (Fig. 10.11), which until 2009 was believed to be the active metabolite [109]. This thiol has three stereogenic centers, namely, the original C(7) of (*S*)-configuration, the C(3)–C(16) double bond of (*Z*)-configuration, and C(4), whose absolute configuration appears to be (*R*).

The recent discovery of a sulfenic acid as the active metabolite of clopidogrel [106] raises the question of the enzymes catalyzing its formation. Indeed, sulfoxidation is a metabolic reaction catalyzed by CYPs as well as flavin-containing monooxygenases (FMOs), of which at least three enzymes exist in humans (FMO1, FMO2, and FMO3) [3,5]. This broadens the prospect of future investigations on the genetic and drug interaction factors that influence clopidogrel activation.

The metabolic pathway of activation of clopidogrel indeed offers opportunities for *genetic factors* and drug-drug interactions (DDIs) to influence its clinical outcome [110]. And indeed, patients taking clopidogrel and who were carrying loss-of-function *CYP2C19* alleles (*2, *3, *4, or *5) were recently found to have a higher rate of cardiovascular event [111]. In healthy subjects administered clopidogrel, carriers of at least one *CYP2C19* loss-of-function allele (30% of the studied population) had a relative

Figure 10.11 A schematic comparison of the mechanism of activation of the anti-aggregating bioprecursors clopidogrel (**28**) and prasugrel (**32**) to their (re)active sulfenic acid metabolite **31** and **35**, respectively. The lower part of the figure shows a mechanism of glutathione-mediated reduction of the sulfenic acid to the corresponding thiol, which was believed for years to be the active metabolite.

reduction of one-third in plasma exposure to the thiol metabolite, a decrease that corresponded to a reduction in maximal platelet aggregation [112]. Other studies showed that reduced-function or loss-of-function alleles of *CYP3A* genes also contributed to the phenomenon of clopidogrel resistance [113].

There are also reports of DDIs in increasing or decreasing clopidogrel activation and activity. Thus, treatment with the antituberculosis drug rifampin (a well-known *CYP3A4* inducer) enhanced clopidogrel activity such that some non- and low responders became responders [113]. In contrast, proton-pump inhibitors (e.g., lansoprazole and omeprazole), which are substrates and inhibitors of *CYP2C19* and *3A4*, negatively affected clopidogrel response and increased platelet aggregation [114].

A recently marketed analogue of clopidogrel (**28**) is *prasugrel* (**32**) [115,116]. In contrast to the former, activation of the latter begins with a CES-catalyzed hydrolysis [117–121]. Indeed, C(2) in prasugrel carries a phenolic oxygen, whose deacetylation allows tautomerization to the thiolactone **33**, a close analogue of 2-oxoclopidogrel (**29**). Formation of the intermediate phenol is demonstrated by the isolation of its *O*-glucuronide in human plasma and urine, as well as in laboratory animals. As for the thiolactone **33**, its activation by sulfoxidation to **34** can be postulated in analogy with that of clopidogrel, followed by hydrolytic ring opening to the active *sulfenic acid metabolite* **35**, which shares the same molecular mechanism of action as the active metabolite of clopidogrel.

Prasugrel is about 10 times more potent than clopidogrel, a fact ascribable to its extensive hydrolysis to the thiolactone **33**. Cytochrome P450 has been known to be involved in prasugrel activation, a finding which at the time was difficult to reconcile with its activation by hydrolysis. The discovery of a reaction of sulfoxidation as a second and key step in the activation of thienopyridines [106] seems to resolve this difficulty, while suggesting also a complementary role for FMOs (see above). The fact that prasugrel activity appears less sensitive than clopidogrel to drug interactions and genetic factors [115] is compatible with this view.

There is one noteworthy stereochemical difference between the two prodrugs, since prasugrel is used as the racemate. As for its thiol metabolite, it was found to occur as four stereoisomers, the two most abundant ones having an (*R*)-configured C(4) atom in addition to the original (*R*)- and (*S*)-configurations at the original center of chirality.

10.5.3 Tirapazamine, a Bioreductive Prodrug

Bioreductive prodrugs are designed to be activated by a metabolic reaction of reduction in target tissues or organisms with a low oxygen concentration. Such a state of hypoxia may favor reduction reactions because of a relative lack of oxygen, but the major factor accounting for the shift toward reduction is the hypoxia-increased expression of genes coding for reductive enzymes. A variety of chemotherapeutic agents (antibacterial, antiparasitic, or anticancer agents) are in fact prodrugs activated by a variety of reductases [122,123]. Such prodrugs include nitroarenes, quinones, amidoximes, platinum(IV) complexes, and *N*-oxides exemplified here with *tirapazamine* (**36** in Fig. 10.12) [124–128].

This much-studied agent is inactivated by two-electron reduction steps catalyzed by quinone reductase, losing its two oxygen atoms. Its activation, in contrast, is to a radical (**37**) by a one-electron reduction catalyzed by NADPH-cytochrome P450 reductase and multiple reductases in the nucleus. Loss of water yields the *benzotriazinyl radical* **38**, whose strong reduction potential allows it to cause DNA single-strand and double-strand breaks, thereby being reduced to **39**. Back oxidation of the radical **37** by molecular oxygen is a reaction of inactivation, which can occur in aerobic cells. In other words, cellular toxicity will depend first and foremost on oxygen levels in the cells. Of interest is also the fact that simple monosubstitution of tirapazamine can alter its lipophilicity enough to markedly improve extravascular transport and activity against target cell [128].

Figure 10.12 Tirapazamine (**36**), a bioreductive antitumor prodrug, and its molecular mechanism of activation to the benzotriazinyl radical **38**, which reacts with DNA.

10.6 METABOLIC DRUG-DRUG INTERACTIONS: THE CASE OF ANTI-HIV PROTEASE INHIBITORS (PIs)

DDIs at the level of metabolism result from drug A inducing or inhibiting one or more enzyme(s) acting on drug B [13]. Other types of DDIs involve interactions at the level of transporters or receptors. As such, DDIs result from a biological system being altered by the action of a xenobiotic, a process we have classified as a PD response. Significantly, this biological response is of indirect interest in our context and offers a perfect illustration of the PK/PD interplay outlined in Section 10.2.1. To illustrate the phenomenon, this section gives a short overview of DDIs produced by or seen among PIs used in antiretroviral therapy. The focus will be on the PI *ritonavir* (RTV), a classical and well-known inhibitor of the metabolism of other drugs [129–133].

RTV was first used at high doses as the sole PI in anti-HIV combinations. Its high toxicity at high doses and a less favorable profile have led to its current use being restricted to that of a pharmaco-enhancer of other PIs such as *atazanavir*, *darunavir* (DRV), *fosamprenavir*, *indinavir*, *lopinavir*, *saquinavir*, and *tipranavir*. Indeed, RTV is a substrate of CYP3A, the efflux transporter P-glycoprotein (P-gp), and to a lesser extent CYP2D6. More importantly, RTV is a potent inhibitor of CYP3A4, an inhibitor of CYP2D6 and P-gp, and a moderate inhibitor of CYP2C9.

The antiretroviral drugs with which RTV is being associated have their own inhibitory effects, resulting in complex effects. For example, the AUC and $C_{\max}$ of the C-C chemokine receptor type 5 (CCR5) antagonist *maraviroc* were increased four- and twofold, respectively, by a DRV-RTV combination [132]. In contrast, the DRV-RTV combination modestly increased or decreased the AUC and $C_{\max}$ of some reverse transcriptase inhibitors. As for agents in other therapeutic classes (e.g., antimicrobials, proton-pump inhibitors, and antidepressants), the effects of the DRV-RTV combination varied from drug to drug. For example, the AUC and $C_{\max}$ of ketoconazole increased two- to threefold, while those of sertraline decreased twofold; smaller effects were seen in the PK behavior of other drugs.

To complicate matters further, RTV is now known to be an enzyme inducer in addition to being an inhibitor [130]. Thus, it is an inducer of CYP3A, although its inhibitory interactions with this enzyme are far more prevalent and may be related to “inhibition-associated induction.” At high doses, RTV induces CYP1A2, thereby increasing the metabolic clearance of theophylline, caffeine, and olanzapine, and CYP2C9 (acenocoumarol, phenytoin, phenobarbital, etc.). At high and low doses, it also induces CYP2B6 (bupropion, meperidine, efavirenz, sertraline, etc.), CYP2C19 (methadone, proton-pump inhibitors, etc.), and UDP-glucuronosyltransferases (zidovudine, raltegravir, valproate, oral contraceptives, oxazepam, morphine, nonsteroidal anti-inflammatory drugs, etc.).

10.7 CONCLUSION

This chapter follows a double thread. Along the main thread, as obvious for the layout, we see the intrinsic activity of the drug decreasing, while that of the metabolite(s) increases. Thus, the reader moves from (i) drugs with no active metabolite (Section 10.2.4) to (ii) drugs having active metabolite(s) (Section 10.3) to (iii) intrinsically inactive prodrugs. For the vast majority of (active) drugs having active

metabolites, bioactivation is found to occur by CYP-catalyzed oxidation, as illustrated here with benzodiazepines, codeine, tramadol, and tamoxifen. Among prodrugs, a discrimination is made between carrier-linked prodrugs, whose activation is by cleavage (generally hydrolytic) of a promoiety (Section 10.4), and bioprecursors (Section 10.5), where a redox reaction creates a pharmacophoric or reactive group.

The second thread in the chapter is that of biological levels of complexity and it may seem to be followed erratically. Indeed, metabolic bioactivation may be discussed at various biological levels, from the molecular and enzymatic to the clinical. Here, there is no logical sequence, but we have tried to achieve a reasonable balance that would appeal to most readers. Depending on the breadth and value of the available information, some examples were indeed focused mainly on clinical outcomes, while others deal in greater details with biochemical aspects. Sometimes a convincing causal link can be deduced between the biomolecular and clinical levels. In other cases, the causal link may fail to be fully convincing, pointing to a need for further studies.

While these were not the proper topic of the chapter, pharmacogenetic differences and DDIs are also briefly discussed and exemplified in later sections. These serve to strengthen the link we tried to draw between the biochemical and the clinical levels of drug metabolism.

11.1 INTRODUCTION

Metabolite-dependent toxicity is an increasingly important issue for the pharmaceutical industry. In particular, the formation of electrophilic reactive metabolites with drug candidates has received much attention, considering that the liability has been associated with genotoxicity, target organ toxicity, drug–drug interactions, and possibly, idiosyncratic adverse drug reactions (IADRs). IADRs constitute a rare, toxic drug reaction found only in the drug-treated patients clinically and is not reproducible in animal experiments [1]. In an increasing number of cases, evidence suggests that this toxicity can be initiated by the production of chemically reactive, electrophilic metabolites, which covalently bind to macromolecules such as proteins and nucleic acids, unless otherwise detoxified by glutathione *S*-transferases or other scavenging phase II drug-metabolizing enzymes [2–6]. The concept of drug metabolism to chemically reactive metabolites that covalently modify proteins leading to toxicity was first demonstrated in the 1970s with the anti-inflammatory agent acetaminophen by Brodie *et al.* at the National Institutes of Health [7–10]. Mechanistic studies that established

Scheme 11.1 P450-catalyzed bioactivation of the anti-inflammatory agent acetaminophen.

the cytochrome P450-mediated bioactivation of acetaminophen to a reactive quinone-imine intermediate [NAPQI (*N*-acetyl-*p*-benzoquinone imine)], capable of depleting the levels of the endogenous antioxidant glutathione (GSH) and/or binding covalently to liver macromolecules (Scheme 11.1) has served as a paradigm for drug toxicity assessment over the decades [11]. Acetaminophen is a major cause of drug-related morbidity and mortality in humans, capable of producing hepatic necrosis after a single toxic overdose [12].

Given the sophistication of twenty-first century bioanalytical methodology, the detection of a bioactivation process can be relatively straightforward; however, the downstream consequences of this metabolic event as it relates to IADRs remain unclear [13,14]. The hapten hypothesis proposes that covalent modification of protein(s) by a reactive metabolite is followed by cleavage to peptide fragments by a proteasome. These peptides are transported to the cell surface after binding to the major histocompatibility complex class I (MHC-I) and presented to the immune system. It is believed that abnormal peptides, when recognized by cytotoxic T-lymphocytes as non-self-peptides, induce the toxic immune reaction finally leading to cell death. If so, then idiosyncrasy would reside on (i) formation of the chemically reactive metabolite, (ii) degradation of the reactive metabolites, (iii) recognition of drug-modified proteins as non-self-proteins by the immune system, and (iv) immune-mediated IADR in susceptible patients [13–16].

Possibly, the most important susceptibility factor for IADRs is genetic variability [17]. Genetic polymorphisms have a strong influence on drug metabolism and may increase risk of IADRs. For example, polymorphism of the *N*-acetyltransferase 2 (NAT2) gene differentiates fast from slow acetylators; the latter have increased susceptibility to toxicity of certain aniline-containing drugs such as isoniazid, sulfamethoxazole, dapsone, and procainamide [18,19]. The major route of elimination of these drugs in humans involves *N*-acetylation of the aniline moiety by NAT2, resulting in the neutral amide metabolites. In an NAT2-deficient population, the aniline motif in isoniazid is hydrolyzed by amidases, liberating hydrazine, which is toxic in its own right; likewise, sulfamethoxazole, dapsone, and procainamide are biotransformed by P450 enzymes to yield cytotoxic and protein-reactive metabolites that include *N*-hydroxyaniline derivatives and the subsequent two-electron oxidation products, that is, the nitroso intermediates. The reactivity of the nitroso metabolites of these drugs with GSH and/or proteins in target organs has also been demonstrated [20–22]. There is also a strong possibility that components of ingested foods, including herbal supplements, can modulate drug metabolism and therefore increase IADR risk [22].

Considering that a detailed understanding of the mechanisms of IADRs remain poorly understood, it is currently impossible to *accurately predict* which new drugs will

be associated with a significant incidence of IADRs, and this poses a significant challenge in drug discovery/development. Despite the disadvantage, there are a few *default* assays in place that could likely reduce the probability of occurrence of IADRs with new drugs. Because it is now widely appreciated that reactive metabolites, as opposed to the parent molecules from which they are derived, are responsible for the pathogenesis of some IADRs, most pharmaceutical companies have implemented procedures to evaluate a drug candidate's potential to undergo metabolic activation (bioactivation), with the goal of eliminating or minimizing reactive metabolite formation by rational structural modification of the lead chemical class.

11.2 SCREENING FOR REACTIVE METABOLITES

Screens for assessing reactive metabolite formation with drug candidates include protein covalent binding studies and/or trapping of reactive metabolites with nucleophiles. Covalent binding studies can be used to quantitatively estimate irreversible incorporation of radioactivity into proteins, following incubation of radiolabeled material with appropriate biological matrix (e.g., NADPH-supplemented liver microsomes) or through direct *in vivo* administration to preclinical species [23]. Either tissue or blood/plasma can be examined for the degree of *in vivo* covalent binding. However, covalent binding may require multiple dosing to establish the true impact since reactive metabolites formed after the first dose may be efficiently trapped by the endogenous antioxidant, GSH, and eliminated from the body. Once GSH is depleted, the extent of covalent binding with cellular macromolecules may increase rapidly, resulting in toxicity. Despite its utility, the technique has limited value in the early lead optimization phase in drug discovery because of the prerequisite need for synthesis of radiolabeled material for every compound of interest.

With the exception of acyl glucuronides and certain cyclic iminium ions, reactive metabolites are unstable and are not detectable in circulation. Their formation *in vitro* and *in vivo* can be inferred from the characterization of stable conjugates derived from reaction with chemical trapping agents. The trapping of reactive metabolites with exogenous nucleophiles to yield stable conjugates amenable to structural characterization by liquid chromatography-tandem mass spectrometry (LC-MS/MS) and/or NMR spectroscopy has been exploited extensively to assess bioactivation potential of drug candidates in early discovery. Qualitative *in vitro* screening of reactive metabolite formation involves "trapping" studies conducted with NADPH-supplemented human liver microsomes and exogenously added GSH. Alternate metabolism vectors, such as liver cytosol, liver S9 fractions, hepatocytes, neutrophils, can be used instead of liver microsomes to probe the contribution of non-P450 enzymes to reactive metabolite formation. GSH adducts are relatively easy to detect by LC-MS/MS since the conjugates display a characteristic loss of 129 Da on collisional activation in MS/MS experiments of the molecular ions [24]. Since 129 Da corresponds to the loss of the pyroglutamate moiety of GSH, monitoring the loss of 129 Da in a constant neutral loss mode provides a generic and selective means to identify GSH adducts. The constant neutral loss scan will provide the molecular weight of the GSH adduct, and subsequent product ion scans can provide structural information about the nature of the adduct. Several modifications to the GSH-trapping assay have been made to accommodate screening of large numbers of compounds that are typically synthesized in discovery [25–28]. The

presence of the soft nucleophilic thiol group in GSH and its derivatives ensures efficient conjugation with soft electrophilic centers on most reactive metabolites (e.g., Michael acceptors including quinonoids, α,β -unsaturated carbonyl compounds, epoxides including arene oxides, alkyl halides) to yield stable thiol conjugates. Reactive metabolites containing hard electrophilic centers (e.g., DNA-reactive aldehydes) will preferentially react with hard nucleophiles such as amines (e.g., semicarbazide and methoxylamine), amino acids (e.g., lysine), and DNA bases (e.g., guanine and cytosine) to afford the corresponding Schiff base [29,30]. Electrophilic iminium species that are generated via metabolism of acyclic and cyclic tertiary amines can be trapped using cyanide anion, which is a hard nucleophile [31,32]. A clear-cut advantage of the reactive metabolite trapping methodology is that it does not require radiolabeled material and is amenable to high throughput screening. As illustrated later, elucidation of the structure of GSH conjugates can provide indirect information on the structure of the reactive metabolite, thereby providing an insight into the bioactivation mechanism and hence a rationale on which to base subsequent chemical intervention strategies.

11.3 STRUCTURE–TOXICITY RELATIONSHIPS

An understanding of the biochemical basis of IADRs has aided to replace the vague perception of a chemical class effect with a sharper picture of individual molecular peculiarity. There are several instances of prototype drugs associated with toxicity, which also form reactive metabolites; elimination of the bioactivation liability in the successor agent also results in elimination of the toxicity associated with the predecessor [33–36]. Although evidence from structure–toxicity analyses is usually anecdotal, a compelling case for chemotype-based liability can be inferred as illustrated with the following examples.

The broad-spectrum antibiotic trovafloxacin has been associated with several cases of clinically symptomatic liver toxicity, including cases of acute liver failure and/or liver-injury-related fatalities. This rare but serious hepatotoxicity led to the withdrawal of trovafloxacin from the market in many countries and a black box warning with intensive monitoring requirements in the United States. With the exception of trovafloxacin, none of the other drugs in the fluoroquinolone class of antibiotics (Scheme 11.2) have been associated with idiosyncratic hepatotoxicity. Grepafloxacin was withdrawn from the market because of concerns over its cardiovascular safety, while the clinical development of clinafloxacin was terminated because of phototoxicity. Ciprofloxacin, levofloxacin, and gatifloxacin remain in the marketplace. From a structure–toxicity standpoint, trovafloxacin contains the cyclopropylamine functionality at the C-7 position of the fluoroquinolone scaffold, a feature absent in other fluoroquinolone-based antibiotics. Studies with a model cyclopropylamine derivative **1** have revealed cyclopropylamine ring bioactivation by P450 and myeloperoxidase (MPO) to a reactive α,β -unsaturated aldehyde **2** trapped as a sulfhydryl conjugate **3** (Scheme 11.2) [37]. The characterization of a hydroxycarboxylic acid metabolite of trovafloxacin (**4**) in preclinical species lends further credence for the metabolism of the cyclopropylamine ring in trovafloxacin to a reactive intermediate [38]. The formation of **4** can occur from addition of water to the α,β -unsaturated aldehyde via Michael addition followed by oxidation, as depicted for the model compound (Scheme 11.2). However, the proposal for reactive metabolite formation with trovafloxacin remains a speculation since

Scheme 11.2 Insights into trovafloxacin bioactivation via the use of a model compound containing the cyclopropylamine functionality.

the bioactivation studies did not involve the parent fluoroquinolone; furthermore, no α,β -unsaturated aldehyde or the corresponding GSH conjugate has been detected in trovafloxacin incubations in human liver microsomes [37]. Also, the primary pathways of trovafloxacin clearance in humans include phase II metabolism (N-acetylation and N-sulfation on the primary amine group and acyl glucuronidation on the carboxylic acid moiety), with very minor contributions from phase I oxidative pathways [39].

In addition to the reactive metabolite theory, microarray analysis revealed substantial gene expression changes following treatment of human hepatocytes with trovafloxacin as compared to other marketed fluoroquinolones [40]. The expression profile induced by trovafloxacin was markedly distinct from other fluoroquinolones, in that genes involved in oxidative stress were regulated consistently by trovafloxacin. In HepG2 cells, trovafloxacin also induced oxidative stress and depleted intracellular GSH levels to a greater extent than other fluoroquinolones [41]. Finally, a potential role of inflammatory mediators in trovafloxacin hepatotoxicity has been recently disclosed [42]. In lipopolysaccharide-pretreated rats that were administered trovafloxacin, accumulation of liver neutrophil (PMN) has been observed. Prior depletion of PMN in the animals attenuated liver injury, confirming the role of PMN in the hepatotoxicity induced by lipopolysaccharide/trovafloxacin.

A second illustration involves a comparison of the inhaled anesthetics, namely, halothane, isoflurane, and desflurane. In susceptible patients, halothane, isoflurane, and desflurane can produce severe hepatic injury by an immune response directed against

reactive acyl halides covalently bound to hepatic proteins [43]. Approximately 20–50% halothane absorbed in the body undergoes metabolism via oxidative and reductive processes, which are catalyzed by P450 enzymes [44,45]. P450 2E1-mediated oxidation of halothane affords a highly unstable halohydrin intermediate, which spontaneously degenerates to yield trifluoroacetyl chloride, capable of reacting with protein and thiol nucleophiles [46,47]. The use of halothane derivatives, isoflurane and desflurane, both of which are only metabolized between 1% and 3%, is associated with a significantly lower incidence of hepatotoxicity. From a structure–toxicity standpoint, the relative incidence of hepatotoxicity appears to directly correlate with the extent of acyl halide formation by P450, which in turn is governed by the leaving group ability of the respective substituents within the drugs. As is seen in Scheme 11.3, halothane, which exhibits the greatest incidence of hepatotoxicity in the clinic, undergoes the most conversion to reactive acyl chloride, a feature that can be attributed to the presence of bromide substituent, which is a good leaving group. In contrast, isoflurane and desflurane also undergo oxidative metabolism resulting in the formation of reactive acyl halides, but the degree to which these anesthetics are bioactivated is significantly lower than halothane [48]. Thus, the lower yield of acylhalide formation with isoflurane may be traced back to changes in the electronic environment that reduce overall affinity toward metabolism or to the relatively poor leaving group ability of the difluoromethoxy group compared to that of bromide.

Antidepressants/antianxiolytics nefazodone and buspirone provide the third example of chemotype-specific toxicity. In the case of nefazodone, idiosyncratic hepatotoxicity resulting in more than 20 deaths has been reported since its introduction in the 1990s [49–51]. Circumstantial evidence linking nefazodone hepatotoxicity with reactive metabolite formation has been established; *para*-hydroxynefazodone, which is a circulating metabolite of nefazodone in humans, is metabolized by P450 3A4 to electrophilic quinonoid species, which are trapped as GSH adducts (Scheme 11.4) [52,53]. In addition, reactive iminium ion intermediates arising from α -carbon oxidation of the piperazine ring and its downstream metabolites have been characterized as stable cyanide conjugates (Scheme 11.4) [32,53]. Incidentally, the nefazodone bioactivation pathway catalyzed by P450 3A4 is also accompanied by mechanism-based

Scheme 11.3 Metabolism of inhaled anesthetics to reactive metabolites.

Scheme 11.4 Reactive metabolite formation pathways with nefazodone (hepatotoxin): comparison with the nonhepatotoxin buspirone.

inactivation of the isozyme [52]. This *in vitro* observation is consistent with nefazodone's nonlinear pharmacokinetics (due to autoinactivation) and clinical drug–drug interactions with P450 3A4 substrates [54–56]. As in the case of nefazodone, *para*-hydroxybuspirone also represents a major circulating metabolite of the anxiolytic agent buspirone (Scheme 11.4) [52]. However, failure to detect GSH conjugates in microsomal incubations of buspirone suggests that *para*-hydroxybuspirone does not succumb to reactive metabolite formation in a manner similar to that observed with *para*-hydroxynefazodone [52]. Absence of reactive metabolite formation with buspirone in a similar manner as nefazodone is consistent with *ab initio* calculations, which suggest that a weaker resonance stabilization of the oxidation products and the greater acidity make *para*-hydroxybuspirone less favorable for the two-electron oxidation (Scheme 11.4). These observations appear to correlate with the lack of idiosyncratic hepatotoxicity with buspirone, despite decades of clinical use. Furthermore, apart from the reactive metabolite liability, nefazodone (in parent form) also exhibits mitochondrial toxicity and is a potent inhibitor of the bile salt export pump (BSEP) transporter, features that are not shared by buspirone [57,58]. The reported cases of cholestasis with nefazodone can be potentially explained in part due to inhibition of the BSEP transporter [59].

Another retrospective analysis involves the anxiolytic agents alpidem and zolpidem. Alpidem was withdrawn from commercial use within the first year of its introduction because of several cases of severe hepatotoxicity, requiring immediate liver transplant and/or leading to fatalities. In contrast, the structural analog and commercial blockbuster drug zolpidem does not possess the hepatotoxic liability. A key structural

Scheme 11.5 Differential metabolism of the anxiolytic agents alpidem (hepatotoxin) and zolpidem (nonhepatotoxin).

difference in the two drugs is the replacement of the two chlorine atoms in alpidem with two methyl groups in zolpidem. In alpidem, the chloro-imidazopyridine ring is subject to P450 bioactivation leading to the formation of a reactive epoxide that reacts with GSH to yield sulfhydryl conjugates (Scheme 11.5), which have been detected in humans [60]. In contrast, zolpidem is metabolized via oxidation of both methyl groups to the corresponding alcohol and carboxylic acid metabolites (Scheme 11.5); GSH conjugates of zolpidem have not been detected in humans [61]. Furthermore, in addition to the bioactivation liability, alpidem also exhibits potent inhibition of mitochondrial respiration and also depletes GSH in primary hepatocyte cultures, phenomena that are not observed with zolpidem even at high concentrations [61].

An equally intriguing example of how a subtle structural difference can influence a toxicological outcome is seen with the dibenzodiazepine derivatives and antipsychotic agents clozapine and quetiapine. While clozapine use is limited by a high incidence of agranulocytosis, hepatotoxicity, and myocarditis, quetiapine does not cause these toxic events. Clozapine exhibits covalent binding to human neutrophil proteins *in vitro*, via myeloperoxidase-mediated oxidation of the dibenzodiazepine ring to a reactive iminium ion, which covalently binds to the target tissues and also reacts with GSH (Scheme 11.6) [62,63]. Proteins covalently modified with clozapine have been observed in neutrophils

Scheme 11.6 Structure-toxicity relationships with antipsychotic drugs clozapine and quetiapine.

of patients being treated with clozapine, which reaffirms the relevance of the *in vitro* studies [64]. In the case of quetiapine, the bridging nitrogen is replaced with a sulfur atom; consequently, this drug is not bioactivated to the reactive iminium species [65]. Despite administration at doses comparable to clozapine, cases of agranulocytosis with quetiapine are extremely rare.

A final and perhaps the most interesting example is highlighted with the nonsteroidal anti-inflammatory drugs (NSAIDs) ibuprofen and ibufenac. While the NSAID ibuprofen is considered to be one of the safest over-the-counter anti-inflammatory agent in the market, its close-in analog ibufenac was withdrawn due to severe hepatotoxicity. The daily doses of both the NSAIDs were comparable, and the only structural difference between the two drugs is the presence of the α -methyl substituent in ibuprofen. Glucuronidation of the carboxylic acid moiety in most NSAIDs constitutes the principal elimination mechanism *in vivo* in humans [66–68]. Carboxylic acid glucuronides (acyl glucuronides) are reactive esters that covalently adduct to macromolecules via two different pathways (Scheme 11.7). The first is a transacylation mechanism, where a nucleophilic amino acid on a macromolecule attacks the carbonyl group of the primary acyl glucuronide leading to the formation of an acylated protein and free glucuronic acid. The second mechanism involves condensation between the aldehyde group of a rearranged acyl glucuronide and a lysine residue or an amine group of the N-terminus, leading to the formation of a glycated protein. The formation of the iminium species is reversible but may be followed by an Amadori rearrangement of the imino sugar to the more stable 1-amino-2-keto product [67,69,70]. A structural relationship between acyl glucuronide degradation to the Schiff base and covalent binding has been established [69,70]. Acyl glucuronides of ibufenac and other acetic-acid-based NSAIDs such as tolmetin and zomepirac, all of which have been withdrawn due to toxicity, exhibit the highest level of rearrangement and covalent binding, whereas mono- α -substituted acetic acids (2-substituted propionic acids) such as ibuprofen and naproxen exhibit intermediate level of acyl glucuronide rearrangement and covalent binding. Overall, these observations imply that inherent electronic and steric properties must modulate the rate of acyl glucuronide rearrangement [71,72]. Thus, in the case of ibuprofen, it is likely that presence of the α -methyl substituent slows the rearrangement of the acyl glucuronide to the electrophilic carbonyl intermediate.

Scheme 11.7 Reaction of acylglucuronides with proteins.

It is noteworthy to point out that most of the successor drugs in the examples discussed above have not evolved from specific tactics to eliminate reactive metabolite liability in predecessor agents. However, these examples imply that by avoiding structural alerts/toxicophores in drug design, one would lessen the odds that a drug candidate will lead to idiosyncratic toxicity due to reactive metabolite formation. Given the inability to predict whether reactive-metabolite-positive compounds will ultimately cause toxicity, a general strategy adopted by many within the pharmaceutical community involves the assessment of reactive metabolite formation as early as possible in the selection of drug candidates; this in turn can influence the rational design of compounds devoid of reactive metabolite formation. In practice, however, this exercise is by no means trivial; medicinal chemistry tactics to eliminate reactive metabolite formation could confer a detrimental effect on primary pharmacology (e.g., changes in agonist/antagonist behavior and/or subtype selectivity for target receptor or enzyme) and/or pharmacokinetic attributes. Thus, chemical intervention strategies to abolish reactive metabolite formation are often an iterative process, the success of which is heavily dependent on a close working relationship between medicinal chemists, pharmacologists, and metabolism scientists.

11.4 EXAMPLES OF MEDICINAL CHEMISTRY TACTICS TO ELIMINATE/MINIMIZE REACTIVE METABOLITE FORMATION

Examples of medicinal chemistry strategies to eliminate reactive metabolite formation in drug discovery are abundant in the primary literature. For instance, the presence of the 2-carboxamidothiazole toxicophore in the nonpeptidyl thrombopoietin receptor agonist **5** led to studies [73] to evaluate reactive metabolite potential of **5** via pathways involving thiazole ring scission in a manner similar to that discerned for the hepatotoxic NSAID sudoxicam [74]. Although the thiazole moiety in **5** did not undergo enzyme-catalyzed ring opening to afford reactive acylthiourea and/or glyoxal metabolites, the corresponding 4-(4-fluoro-3-(trifluoromethyl)phenyl)thiazol-2-amine (**6**), the product of carboxylesterase-mediated hydrolysis of **5** in human hepatic tissue and plasma, underwent oxidative bioactivation in human liver microsomes since trapping studies with GSH led to the formation of two conjugates derived from the addition of the thiol nucleophile to **6** and a thiazole-*S*-oxide metabolite of **6** (Scheme 11.8). Mass spectral fragmentation and NMR analysis indicated that the site of attachment of the glutathionyl moiety in both conjugates was the C-5 position in the thiazole ring. On the basis of the structures of the GSH conjugates, two bioactivation pathways were proposed, one involving β -elimination of an initially formed hydroxylamine metabolite and the other involving direct two-electron oxidation of the electron-rich 2-aminothiazole system to electrophilic intermediates. The mechanistic insights gained from the metabolism studies influenced subsequent medicinal chemistry strategies, which involved blocking the C-5 position with a fluorine atom (**7**) or replacing the thiazole ring with a 1,2,4-thiadiazole group (**8**) (Scheme 11.8). These structural changes not only abrogated the bioactivation liability associated with **5** but also resulted in compounds that retained the attractive pharmacological and pharmacokinetic attributes of the prototype agent.

A second example, which focuses on eliminating reactive metabolite liability within a chemical series, is evident in the recent work of Hartz *et al.* [75] on pyrazinone-based corticotrophin releasing factor 1 receptor antagonists and potential antidepressant/

Scheme 11.8 Medicinal chemistry strategies to eliminate reactive metabolite formation with a nonpeptidyl thrombopoietin receptor agonist **5** containing the 2-aminothiazole toxicophore.

antianxiolytic drugs. The attractive *in vivo* pharmacology and disposition properties of the pyrazinone derivative **9** (Scheme 11.9) were offset by the finding that **9** was bioactivated by P450 to form reactive metabolites. In fact, a major component of the elimination mechanism of **9** in rats (~40% of drug-related material recovered in rat bile) is composed of conjugation with GSH, which is consistent with reactive metabolite formation *in vivo* [76]. Two distinct bioactivation pathways were deciphered (Scheme 11.9): (i) oxidative metabolism on the chloropyrazinone ring to yield an electrophilic epoxide and (ii) O-dealkylation of the difluoromethoxy moiety to yield a phenol metabolite **10**, two electrons in which generated the reactive quinone-imine species in a manner similar to that discerned with the 2,6-dichloro-4-hydroxyaniline analogs and NSAIDs diclofenac and lumiracoxib [77,78]. On the basis of this information, medicinal chemistry strategies were put in place to eliminate reactive metabolite liability in **9**. To eliminate bioactivation of the 2,6-dichloroaniline motif,

Scheme 11.9 Minimization of reactive metabolite formation with a pyrazinone-based corticotropin releasing factor 1 receptor antagonist **9**.

efforts were directed toward incorporation of a pyridyl group as an bioisosteric replacement. To reduce the level of 5-chloropyrazinone ring bioactivation, attempts were made to replace chlorine with the more strongly electron-withdrawing cyano group. Out of this iterative medicinal chemistry exercise emerged **11** (Scheme 11.9) with sufficiently diminished reactive metabolite formation in both rat and human liver microsomes. Consistent with the *in vitro* finding, <2–4% of GSH conjugates was recovered from rat bile following *in vivo* administration of **11**. Compound **11** also retained all the primary pharmacology and pharmacokinetic properties of the lead compound **9**.

Strategies toward eliminating metabolic activation of the electron-rich 4-hydroxyaniline motif have also been described by Park *et al.* on the antimalarial agent amodiaquine [79–83]. The clinical use of amodiaquine is somewhat restricted by several cases of hepatotoxicity and agranulocytosis; the detection of IgG antibodies in patients exposed to the drug is consistent with an immune-mediated hypersensitivity reaction [84,85]. Immune-mediated toxicity is believed to arise from the metabolism of amodiaquine to a reactive quinone-imine species that can covalently bind to cellular proteins or GSH (Scheme 11.10). Exchanging the C'-4-phenolic OH group with a fluorine results in **12** that does not undergo the obligatory two-electron oxidation process to form a electrophilic quinone-imine species (Scheme 11.10) [81]. An alternate approach to prevent reactive metabolite formation involved the isomerization of the 3' and 4' substituents in amodiaquine; from this exercise emerged analogs **13** and **14**, which were devoid of reactive metabolite formation (judged from the lack of formation of thiol conjugates) and possessed pharmacodynamic, pharmacokinetic, and safety profiles comparable to amodiaquine (Scheme 11.10) [82,83].

Scheme 11.10 Rational design of analogs of the antimalarial agent amodiaquine based on metabolism data.

Finally, against this backdrop, it is noteworthy to comment on the metabolism-guided design of fluorofelbamate as a potentially safe alternative to the anticonvulsant felbamate, which is associated with many cases of life-threatening aplastic anemia and hepatotoxicity, resulting in a black box label warning and extensive monitoring requirements in the United States [86]. Evidence linking reactive metabolite formation with felbamate toxicity has been presented by means of the *in vivo* characterization of mercapturic acid (downstream metabolites of GSH) conjugates of a highly reactive α,β -unsaturated carbonyl derivative 2-phenylpropenal, following felbamate administration to rats and humans [87,88]. A mechanism that is consistent with the conversion of felbamate to 2-phenylpropenal is depicted in Scheme 11.11 and involves a carboxylesterase-mediated hydrolysis of one of its carbamate groups to afford the primary alcohol metabolite, oxidation of which by alcohol dehydrogenase (ALD) to the intermediate aldehyde derivative followed by spontaneous β -elimination of the remaining carbamoyl group generates 2-phenylpropenal [87]. On the basis of this information, fluorofelbamate (Scheme 11.11) was specifically designed to eliminate the reactive metabolite liability of felbamate. Fluorofelbamate does not succumb to bioactivation because the fluorine atom prevents the β -elimination process that leads to the reactive 2-phenylpropenal [89]. Whether absence of bioactivation translates into a reduced risk of toxicity remains to be seen. Fluorofelbamate is currently undergoing clinical trials as an antiepileptic agent [90].

Scheme 11.11 Mechanism of reactive metabolite formation with the anticonvulsant agent felbamate: a rational chemical approach to circumvent bioactivation.

Scheme 11.12 Metabolism of atorvastatin into potentially reactive metabolites (and precursors thereof).

11.5 SHOULD INCORPORATION OF TOXICOPHORES BE PROHIBITED IN DRUG DESIGN?

The vast majority of drugs possess a phenyl ring that can be considered as a toxicophore since P450-catalyzed metabolism of the phenyl ring to a phenol proceeds through an electrophilic epoxide species. GSH conjugates of aromatic ring epoxides have been characterized with several toxic drugs (e.g., alpidem), and as such, the bioactivation sequence is the underlying cause of carcinogenic and/or hepatotoxic effects of organic solvents such as benzene and bromobenzene [91,92]. So from a practical standpoint, it is impossible to avoid a toxicophore in drug design. As such, avoiding toxicophores (other than a phenyl group) altogether in early drug discovery can lead to a missed opportunity to develop potentially important medicines. Certainly, this is the case with atorvastatin (Lipitor[®]), which not only contains the acetanilide toxicophore but also metabolism by P450 results in the formation of acetaminophen-like metabolites (Scheme 11.12) [93]. In addition, glucuronidation of its carboxylic acid moiety results in the formation of the potentially electrophilic acyl glucuronide, the likes of which have been implicated in the toxicity associated with the carboxylic acid-containing NSAIDs (Scheme 11.12) [94].

It is further interesting to note that some blockbuster drugs require reactive metabolite formation for pharmacological activity; this is achieved through the introduction of

Scheme 11.13 Bioactivation of clopidogrel (Plavix[®]) to a reactive metabolite, a prerequisite for pharmacological activity.

a toxicophore in the chemical architecture. For instance, the blockbuster cardiovascular drug and P2Y₁₂ antagonist clopidogrel (Plavix[®]) is by itself inactive and requires P450-catalyzed bioactivation of its thiophene ring to form a reactive thiol metabolite, which forms a covalent disulfide bond with a cysteinyl residue on the P2Y₁₂ receptor in platelets (Scheme 11.13), a phenomenon that gives rise to its beneficial cardiovascular effects [95,96].

11.6 VALUE OF REACTIVE METABOLITE TRAPPING AND COVALENT BINDING STUDIES IN THE PREDICTION OF DRUG TOXICITY

While detection of conjugates (GSH, amino, and/or cyano) and/or covalent binding to target tissue (e.g., NADPH-supplemented liver microsomes) provides evidence for reactive metabolite formation, the data needs to be placed in proper context before making a decision on discarding a drug candidate associated with this liability. First and foremost, *a complete lack of reactive metabolite formation and/or covalent binding to liver microsomal protein is not a guarantee of a drug candidate's safety*. Reactive metabolite formation via non-P450-mediated pathways will not display a positive response in liver microsomes fortified with NADPH to test for P450 activity. For example, the felbamate bioactivation process in humans, which leads to the formation of an electrophilic α,β -unsaturated aldehyde, has never been replicated in human hepatic tissue. At therapeutically relevant concentrations of radiolabeled felbamate in *in vitro* incubations with human liver microsomes and human hepatocytes, no GSH adducts (Kalgutkar and Obach, unpublished findings) and/or covalent binding of felbamate has been discerned [97,98]. Although the reason(s) for this discrepancy remains unclear at present, in a drug discovery paradigm relying solely on reactive metabolite trapping and liver microsomal covalent binding as a means of predicting IADR potential of drug candidates, felbamate would have passed the hurdle with flying colors. Likewise, there is no *in vitro* and/or *in vivo* evidence suggestive of reactive metabolite formation with ximelagatran, the first orally active thrombin inhibitor that has been withdrawn from commercial use because of several cases of hepatotoxicity [99,100]. As such, ximelagatran does not contain any structural alerts, and its *in vivo* biotransformation in animals and humans consists of innocuous pathways involving ester hydrolysis and reduction of the amidoxime motif to afford the active ingredient melagatran (Scheme 11.14) [101]. Finally, the possibility that toxicity can arise from mechanisms other than reactive

Scheme 11.14 Metabolism of the thrombin inhibitor and hepatotoxin ximelagatran.

metabolite formation (e.g., direct mitochondrial toxicity) also needs to be taken into consideration. For instance, the finding that alpidem is a potent mitochondrial toxin and zolpidem is not can be used to rationalize the lack of hepatotoxicity associated with alpidem [61]. Similarly, the hepatotoxin nefazodone is associated with mitochondrial toxicity and inhibitory effects on BSEP transporter in the parent form, whereas the nonhepatotoxin buspirone does not lead to these liabilities; these are phenomena that can explain the differences in safety profile of the two antidepressants.

Although covalent binding studies have an advantage over the reactive metabolite trapping studies, in that they provide a quantitative estimate of covalently bound drug to proteins and therefore an indirect measure of reactive metabolite formation, *there are no studies to date that have shown a correlation between the extent of covalent binding and/or reactive metabolite formed and the probability that a drug will be associated with a high incidence of IADRs*. There are numerous examples of blockbuster drugs that are false positives in these assays, that is, they form GSH conjugates and display a degree of protein covalent modification, yet they are not associated with a significant incidence of toxicity. A striking example of this phenomenon is evident with the acetaminophen regioisomer, 3'-hydroxyacetanilide, that undergoes bioactivation yielding reactive metabolites that covalently adduct to GSH and proteins [102]. However, despite dose normalization to provide comparable levels of covalent binding *in vivo* in mice, 3'-hydroxyacetanilide does not exhibit the hepatotoxicity observed with acetaminophen. Furthermore, from a predictive standpoint, as a property itself, covalent binding *in vitro* has not been rigorously tested for its ability to distinguish between toxic and nontoxic drugs, primarily because nontoxic drugs have not been tested in covalent binding studies [23,103]. We have tested the ability of covalent binding measurements in predicting idiosyncratic hepatotoxicity by examining the binding of 18 drugs (9 hepatotoxins and 9 nonhepatotoxins) to human hepatic tissue, taking into consideration key factors such as reactive metabolite detoxication, relative importance of bioactivation leading to covalent binding versus overall metabolism, and daily dose for each drug [97,98]. While most of the hepatotoxic drugs (e.g., acetaminophen, nefazodone, tienilic acid) demonstrated covalent binding to some degree or the other, of great surprise were the findings that several nonhepatotoxic, commercially successful drugs such as buspirone, diphenhydramine, meloxicam, paroxetine, propranolol, raloxifene, and simvastatin demonstrated covalent binding. A quantitative comparison of covalent binding *in vitro* intrinsic clearance did not separate the two groups of compounds, and in fact, paroxetine and diphenhydramine, both nonhepatotoxins, showed the greatest amount of covalent binding in microsomes. Including factors such as the fraction of total metabolism represented by covalent binding and the total daily dose of each drug improved the discrimination between hepatotoxic and nonhepatotoxic drugs in liver microsomes, S9 fraction, and hepatocytes; *however, the approach still would falsely identify some agents as potentially hepatotoxic*. In the case of paroxetine, mechanistic studies further confirmed the importance of parallel metabolic and detoxication pathways in attenuating covalent binding to proteins [104]. As shown in Scheme 11.15, the catechol metabolite obtained via ring scission of the 1,3-benzodioxole group in paroxetine can partition between O-methylation by catechol-O-methyltransferase or undergo oxidation to the reactive quinone intermediate, which is efficiently detoxicated by GSH; both pathways lead to a significant reduction in covalent binding. In humans, the O-methylated catechol derivatives constitute the principal metabolic fate of the drug. When coupled with the

fact that the daily dose of paroxetine is low (20 mg), one gets some insight into the excellent safety record of this drug, despite the bioactivation liability.

The examples discussed above pose a significant challenge toward the reliability of structural alerts, reactive metabolite trapping, and covalent binding measurements as predictors of idiosyncratic toxicity with new drug candidates. With regard to reactive metabolite formation potential, it is very important to consider factors that will influence the metabolism of structural alerts such as the presence of alternate metabolic soft spot(s) that competes with reactive metabolite formation and the existence of detoxication pathways that scavenge the reactive metabolite and/or its precursor. The importance of the first factor was illustrated earlier with the anxiolytic agents alpidem and zolpidem (Scheme 11.5). While bioactivation via epoxidation is also likely in zolpidem, the molecule does not undergo this metabolic fate; instead, the two methyl groups function as metabolic soft spots and are oxidized to the corresponding alcohol and carboxylic acid metabolites. With regard to the importance of competing, detoxication pathways, reactive metabolite formation may be discernible in standard *in vitro* systems, but the principal clearance mechanism of the drug *in vivo* may involve a distinctly different and perhaps more facile metabolic fate that does not yield reactive intermediates. This is illustrated with the selective estrogen receptor modulator raloxifene, which is known to undergo *in vitro* P450 3A4-catalyzed bioactivation on its phenolic groups to yield reactive quinonoid species; however, *in vivo*, glucuronidation of the same phenolic groups in the gut and liver constitutes the principal elimination mechanism of raloxifene in humans (Scheme 11.16) [105–107]. Thus, the likelihood of raloxifene bioactivation *in vivo* is in question when compared with the phase II glucuronidation process, a phenomenon that may provide an explanation for the extremely rare occurrence of IADRs.

11.7 DAILY DOSE/LOW SYSTEMIC REACTIVE METABOLITE EXPOSURE AS A MITIGATING FACTOR FOR IADRs

Anecdotal evidence pinpoints daily dose as a key factor in migrating IADR risks. As such, there do not appear to be examples of drugs that are dosed at <20 mg/day that

Scheme 11.15 Competing metabolic pathways of the antidepressant paroxetine. Plausible explanation for lack of IADRs despite reactive metabolite formation.

Scheme 11.16 Bioactivation and competing detoxication pathways of the selective estrogen receptor modulator raloxifene.

cause IADRs (whether or not these agents are prone to bioactivation). It is likely that the improved safety of low dose drugs arises from a marked reduction in the total body burden to reactive metabolite exposure via efficient scavenging by GSH and therefore unlikely to exceed the threshold needed for toxicity. For example, olanzapine (Zyprexa®) (Fig. 11.1) forms a reactive iminium metabolite very similar to the one observed with clozapine, yet olanzapine is not associated with a significant incidence of agranulocytosis [64,108]. One difference between the two drugs is the daily dose; clozapine is given at a dose of >300 mg/day, while the maximum recommended daily dose of olanzapine is 10 mg/day. A second illustration of this concept is evident on comparison of the thiazolidinedione derivatives troglitazone, rosiglitazone, and pioglitazone. While rosiglitazone has been associated with several cases of cardiotoxicity, the idiosyncratic hepatotoxicity associated with troglitazone, which led to its withdrawal from the market, has not been observed with rosiglitazone as well as pioglitazone. As noted earlier, both the chromane and the thiazolidinedione ring systems in troglitazone succumb to P450 3A4-catalyzed bioactivation to form reactive metabolites [109,110]. While rosiglitazone and pioglitazone do not contain the chromane ring system found in troglitazone, they do contain the thiazolidinedione scaffold. Consistent with the findings with troglitazone, both rosiglitazone and pioglitazone have been shown to undergo thiazolidinedione ring scission mediated by P450 enzyme(s) in human microsomes, resulting in reactive metabolites that are trapped by GSH [111,112]. While bioactivation of the thiazolidinedione ring is a common theme in these drugs, a key difference lies in their daily doses—troglitazone at 200–400 mg/day and rosiglitazone and pioglitazone both at <10 mg/day. Additional examples of this phenomenon are illustrated with tadalafil (Cialis®) and the antihypertensive prazosin (Minipress®) (Fig. 11.1). The methylenedioxyphenyl group in tadalafil undergoes P450 3A4-catalyzed bioactivation to an electrophilic catechol, a process that also leads to the suicide inactivation of P450 3A4 activity *in vitro* [113]. However, to date, there are no reports of IADRs or P450 3A4 drug–drug interactions associated with tadalafil use at the recommended dose of 10–20 mg/day. Likewise, there are no reports of IADRs with prazosin at the recommended daily dose of 1 mg/day, despite the bioactivation of the pendant furan ring to electrophilic intermediates, which can be trapped with semicarbazide and GSH [114].

Figure 11.1 Examples of low daily dose drugs devoid of IADRs, despite bioactivation liability.

11.8 CONCLUDING REMARKS

The issue of reactive metabolites continues to receive widespread interest in the pharmaceutical industry. GSH-trapping assays in human liver microsomes are being incorporated into the discovery screening funnel early on to assess the risk of reactive metabolite formation. Early knowledge concerning bioactivation liability with a chemical series allows an insight into the structure–reactive metabolite relationships and the promise to deliver superior early development candidates. However, as discussed in this chapter, interpretation of the output from these assays is confounded by the fact that many successfully marketed drugs are positive in GSH-trapping assays. Therefore, caution must be exercised in deprioritizing a compound based on a positive result, so that the development of a useful and potentially profitable compound will not be unnecessarily halted. Appropriate consideration also must be given for drug candidates intended to treat previously unmet medical needs. Available evidence suggests that detection of reactive metabolites within a chemical series does not warrant an instant demise of the compounds per se, but it does trigger some additional due diligence including the evaluation of competing detoxication pathways of the reactive metabolite and/or its precursor by phase I/phase II enzymes and an estimation of the human dose based on pharmacokinetic/pharmacodynamic studies in preclinical species. GSH conjugation to reactive metabolites is not necessarily a bad attribute; instead, it reaffirms the ability of the endogenous sulfhydryl antioxidant to efficiently scavenge the electrophilic reactive intermediate. It is only in cases where the concentration of the reactive metabolite formed is so high that it depletes the endogenous antioxidant pool leading to toxicity, as has been demonstrated with acetaminophen. The ability to predict the potential of a drug candidate to cause IADRs is dependent on a better understanding of the pathophysiological mechanisms of such reactions. IADRs are too complex to duplicate in a test tube, and their idiosyncratic nature precludes prospective clinical studies. Genetic factors also appear to have a crucial role in the induction of IADRs. Until we develop a better understanding of the risk of idiosyncratic toxicity arising from the formation of reactive metabolites, the advancement of potent (low dose) drug candidates with only a limited propensity to form reactive intermediates would appear to be the most favored strategy in an ideal world.

12.1 SUMMARY

There is a large amount of circumstantial evidence that supports the hypothesis that most idiosyncratic drug reactions (IDRs) are caused by reactive metabolites rather than the parent drug. When the total daily dose is included in the calculation, there is a rough correlation between the amount of covalent binding and the risk that a drug will be associated with a significant incidence of IDRs, especially those affecting the liver. However, there are drugs that form a large amount of reactive metabolites and rarely cause IDRs, and there are drugs such as ximelagatran that do not appear to form reactive metabolites and yet had to be withdrawn from the market because of an unacceptable risk of IDRs.

There are a wide variety of proteins that are targets of covalent binding, and clearly, not all covalent binding is associated with the same risk of causing an IDR. It is likely that most IDRs are immune mediated, although this is not without controversy, especially with respect to idiosyncratic liver toxicity. There are several hypotheses that address the issue of how drugs initiate an immune response, but in the absence of valid animal models, they are very difficult to rigorously test. These hypotheses include the hapten hypothesis, the danger hypothesis, the p-I (pharmacological interaction) hypothesis, epigenetic effects leading to activation of the immune system, direct activation of antigen-presenting cells, and some of the newer biological agents simply appear

to alter the balance in the immune system and do not involve reactive metabolites. It is likely that the mechanism by which different drugs induce an immune response is different, at least in detail. There are also hypotheses that do not involve the immune system such as mitochondrial toxicity and the inflammagen hypothesis.

In the absence of valid animal models, it is important to use the clinical characteristics of IDRs to evaluate the hypotheses. A very important characteristic is the usual delay between starting a drug and the onset of the IDR. Another important characteristic is that different drugs can cause different types of IDRs in different people and even the same drug can cause different types of IDRs in different people. This is most easily explained by an immune mechanism in which this variability is due to variability in T-cell-receptor specificity, which is different even in identical twins. However, until we have a much better understanding of the detailed mechanisms of IDRs, it will be difficult to predict which drug candidates are likely to cause a relatively high incidence of IDRs and which patients are at high risk of such adverse reactions.

12.2 BACKGROUND

Adverse drug reactions are a major source of patient morbidity and mortality [1]. The most common type of adverse drug reaction involves an extension of the therapeutic effect (i.e., pharmacodynamics) of the drug, for example, warfarin-induced bleeding. In principle, such adverse reactions are predictable and preventable, but in practice, that can be difficult. Less common but making up about 10–20% of adverse reactions are idiosyncratic. Although less common, IDRs are often serious, even life threatening, and their unpredictable nature makes them very hard to deal with. Attempts to avoid IDRs also add significant cost and uncertainty to drug development [2].

There is no universal definition for IDRs [3]. Idiosyncratic means particular to an individual, and therefore, IDRs do not occur in most patients with normal use of a drug. It is the mechanistic implications of the term that are inconsistent. The term *hypersensitivity reaction* is often used for these adverse reactions, but it implies that the reactions are immune mediated, and in the absence of definitive evidence, the term *idiosyncratic* should be used. However, it is confusing because when allergists and clinical immunologists use the term *idiosyncratic drug reaction*, it usually excludes any adverse reaction that is immune mediated, and most IDRs appear to be immune mediated. In this chapter, adverse reactions that involve the therapeutic effects of the drug, such as warfarin-induced skin necrosis, are not discussed, even though such reactions can certainly be particular to an individual. Until we have a better mechanistic understanding of IDRs the term will be vague, and when the mechanisms are clear, the term may become obsolete.

12.3 ASSOCIATION BETWEEN THE FORMATION OF REACTIVE METABOLITES AND THE RISK OF IDRs

The work by the Miller and others [4] demonstrated that the ability of many chemicals to induce cancer was based on their ability to form chemically reactive metabolites that bind to DNA. This concept was translated to adverse drug reactions when it was discovered that acetaminophen-induced liver toxicity is caused by a reactive metabolite [5]. It is clear that drug-induced anaphylaxis is mediated by IgE antibodies

against drug-modified proteins. In the case of penicillin, the parent drug is reactive and no reactive metabolite is required, but in most cases, it is a reactive metabolite of the drug that results in the drug-modified protein [6]. In general, contact hypersensitivity is also caused by chemically reactive species [7]. Other types of drug-induced skin rashes also appear to be due to reactive metabolites [8]; however, it is difficult to prove that most IDRs are caused by reactive metabolites. Most of the evidence is circumstantial, such as in a series of gaseous anesthetics (halothane, isoflurane, and desflurane), there is a correlation between the amount of reactive metabolite formed and the incidence of idiosyncratic liver toxicity [9]. By their very nature, most reactive metabolites bind to targets close to where they are formed. The highest concentration of drug-metabolizing enzymes is in the liver, and this is presumably why hepatotoxicity is the most common type of IDR leading to drug candidate failure or withdrawal from the market. Therefore, in an attempt to “derisk” drug development, drug candidates have been screened for reactive metabolites that covalently bind to protein [10]. If the total daily dose is included in the calculation, there is a correlation between the amount of covalent binding of reactive metabolite and the risk that a drug will cause idiosyncratic liver toxicity; however, the correlation is far from perfect [11,12]. Therefore, it appears that not all covalent binding is associated with the same IDR risk, as discussed in Section 12.6.2. In addition, some drugs such as ximelagatran, pyrazinamide, and allopurinol are associated with a significant incidence of IDRs, and yet, they do not appear to form reactive metabolites (Utrecht JP, unpublished observations) [13].

12.4 CLINICAL CHARACTERISTICS OF IDIOSYNCRATIC DRUG REACTIONS

Given that we have few valid animal models and it is impossible to do controlled experiments in humans to study IDRs, it is important to gain mechanistic clues from the clinical characteristics of IDRs. In fact, it is essential for any mechanistic hypothesis to be consistent with the clinical characteristics/manifestations of these adverse reactions. One very important characteristic of IDRs is that, with few exceptions, there is a delay between starting the offending drug and the onset of the IDR unless there has been previous exposure to the drug [3]. In fact, because the exposure to halothane is brief, even though exposure to halothane-modified proteins is presumably much longer than exposure to the parent drug, halothane-induced hepatotoxicity almost always occurs after more than one exposure [14]. An often-stated characteristic is that IDRs are dose independent—this is not true. What is true is that most patients will not have an IDR at any dose, and because, by definition, the mechanism does not involve the therapeutic effect of the drug, there is no reason that the dose–response relationship in susceptible patients for the IDR will fall in the same range as that for the therapeutic effects. In fact, there is always a dose below which no patient will have an IDR [3].

It is also important to note that different people can have IDRs involving the same drug and having different characteristics, which presumably reflects differences in the mechanism of the IDR in different people [15]. Another important observation is that most drugs that can cause a relatively high incidence of a specific type of IDR can cause several different types of IDRs, although the spectrum can be different for different drugs (Table 12.1). This suggests that some types of structures are prone to causing

TABLE 12.1 Drugs Associated with Multiple Types of IDR

Drug	Structure	Reactive Metabolite	Idiosyncratic Reaction
Procainamide		Aromatic amine oxidized to hydroxylamine, nitroso metabolites, and <i>N</i> -chloramine [16,17]	Agranulocytosis [18] Lupus [19] Thrombocytopenia [20] Red cell aplasia [21]
Sulfamethoxazole		Aromatic amine oxidized to hydroxylamine, nitroso metabolites, and <i>N</i> -chloramine	DRESS [22] SJS/TEN Lupus [23] Agranulocytosis [22] Thrombocytopenia DILI
Aminogluthethimide		Aromatic amine oxidized to hydroxylamine, nitroso metabolites, and <i>N</i> -chloramine	Agranulocytosis [24] DILI Lupus [25] Pancytopenia [26]
Dapsone		Aromatic amine oxidized to hydroxylamine, nitroso metabolites, and <i>N</i> -chloramine	Agranulocytosis [27] Aplastic anemia [28] DRESS [29]

Nomifensine

“?” denotes that the reactive metabolite is not clear.

IDRs, and this is consistent with the ability of some drugs to be metabolized to reactive metabolites, which can lead to different types of IDRs. The following sections are a description of the major types of IDRs.

12.4.1 Autoimmunity

By definition, autoimmunity is an immune response against “self.” Many, if not most, chronic diseases have a strong autoimmune component. These diseases include type I diabetes, multiple sclerosis, rheumatoid arthritis, inflammatory bowel disease, autoimmune thyroiditis, systemic lupus erythematosus, and myasthenia gravis. Even diseases such as arteriosclerosis and Alzheimer’s disease may have an autoimmune component. Drugs can also precipitate an autoimmune response.

12.4.1.1 Generalized Autoimmunity (Lupus-Like Syndrome). Several drugs cause a generalized autoimmune syndrome that resembles idiopathic systemic lupus erythematosus [143]. Although drug-induced lupus is usually milder than idiopathic lupus and usually resolves when the drug is discontinued, there are no absolute criteria that separate idiopathic and drug-induced lupus [144]. The drug associated with the highest incidence of a lupus-like syndrome is procainamide. Almost all patients treated with procainamide for an extended period develop antinuclear antibodies, and about 20% of patients develop clinically evident autoimmunity, although the manifestations are usually less severe than those of idiopathic lupus [144]. Patients are often treated with procainamide for more than a year before the onset of symptoms, but once the drug is stopped, the symptoms usually resolve in a matter of weeks, even though, being an autoimmune syndrome, the antigens are still present.

Procainamide is oxidized by macrophages to reactive hydroxylamine and nitroso metabolites, and this has the potential to activate macrophages [145]. This could be involved in the mechanism of autoimmunity, and most of the drugs that cause a lupus-like syndrome are also oxidized to reactive metabolites by macrophages [146]. In addition, procainamide and hydralazine also inhibit DNA methylation, which can lead to lymphocyte activation, and this could also play an essential role in the induction of autoimmunity, at least for these two drugs [147]. We have found that penicillamine, isoniazid, and hydralazine, which also induce lupus-like syndrome, react with carbonyl groups on macrophages and lead to their activation [148,149]. This is likely to play an essential role in the ability of these drugs to induce autoimmunity. There are many new biological drugs that inhibit various arms of the immune system, which have been developed to treat autoimmune diseases such as multiple sclerosis and inflammatory bowel disease. Paradoxically, most of these drugs can also induce autoimmunity, presumably by altering the delicate balance of the immune system [150].

12.4.1.2 Organ-Specific Autoimmunity. There are several drugs that cause an autoimmune reaction that is limited to one organ. Examples include α -methyl dopa-induced hemolytic anemia and nitrofurantoin- and minocycline-induced autoimmune hepatitis. These syndromes are described in greater detail below.

12.4.2 Skin Rash

The most common type of IDR is the skin rash. It is likely that this is because the skin acts as a barrier to the outside world and is immunologically very reactive. Furthermore,

on the basis of their clinical characteristics and histology, it is likely that virtually all skin rashes are immune mediated [151]. Rashes can vary from a mild maculopapular rash to very severe rashes such as toxic epidermal necrolysis (TEN) in which a large portion of the skin basically dies, and TEN is associated with a high (~30%) mortality rate.

If skin rashes are commonly caused by reactive metabolites, which seems likely, an important question is whether the reactive metabolite must be formed in the skin. In the case of penicillin, it is the parent drug that is chemically reactive, but its reactivity is low so that it can freely circulate and local reactive metabolite formation is not required. Most reactive metabolites are formed by cytochrome P450s, and although low levels of these enzymes are present in the skin [8], it is not clear that sufficient P450-mediated metabolism occurs in the skin to induce an immune response. Probably, the best evidence is for fragrances that can cause contact hypersensitivity reactions. Some undergo spontaneous oxidation to reactive species, but others require metabolic activation [152]. Macrophages and other antigen-presenting cells, which are present in the skin, contain myeloperoxidase that can oxidize some drugs to reactive metabolites, and given their importance to an immune response, reactive metabolite formation of some drugs by these cells could result in an immune response [153,154]. The activity of some metabolic enzymes in the skin, such as sulfotransferases, is high, and there are some cases in which sulfation can lead to a reactive metabolite [155,156]. It is also possible that an immune response is initiated elsewhere in the body, and the skin becomes a bystander because of its high immunosurveillance activity. This is consistent with the observation that a reactive metabolite may be responsible for initiating an immune response, but then the immune response spreads so that lymphocytes recognize the parent drug [157]. Although drugs can cause other types of rashes, such as fixed drug eruptions, the discussion is limited to urticaria, maculopapular rashes, and Stevens–Johnson syndrome/TEN.

12.4.2.1 Urticaria. Otherwise known as *hives*, urticaria is classically an allergic reaction mediated by IgE antibodies. When it is caused by drugs such as penicillin it is mediated by IgE antibodies against drug-modified proteins [158]. This is a classic case of a drug or reactive metabolite acting as a hapten to modify protein, and in some patients, this leads to an immune response. This is a clear case where chemical reactivity of the drug or metabolite is an essential aspect of the mechanism. In the case of penicillin, this can be demonstrated by skin tests in which a small amount of penicillin-modified polylysine is injected into the skin and results in an immediate wheal and flare response in sensitive patients, which is mediated by IgE antibodies. Penicillin binds to proteins in all patients, and it probably induces an antibody response in most patients; however, in most cases, this immune response is predominantly an IgG response, which does not result in an adverse reaction. It is only when the immune response is predominantly an IgE response, leading to a sufficient concentration of IgE antibodies, that urticaria results.

Some patients have what is called *chronic urticaria* in which they can have daily episodes of urticaria not precipitated by any known drug or chemical exposure. This condition is not well understood, but it appears to represent an autoimmune reaction [159]. In some cases, chronic urticaria appeared to follow a typical allergic reaction to a drug, and it may be that in these cases, this allergic reaction triggered an autoimmune reaction resulting in chronic urticaria. In some patients, urticaria can be induced by

cold or exercise; obviously, there are no antibodies against cold. Therefore, urticaria is not always a true allergic reaction to a chemical allergen.

12.4.2.2 Maculopapular Rash. The most common type of rash induced by drugs is a maculopapular or morbilliform rash. This can be an isolated finding, or it can be part of a more general response to a drug such as the generalized hypersensitivity reactions described below. In many cases, this rash resolves despite continued treatment with the drug. In general, drugs that cause more serious rashes such as TEN in some patients will cause maculopapular rashes at a higher frequency than the more severe rashes, and early in the course of the rash, it can be difficult to differentiate the two. However, some drugs commonly cause maculopapular rashes and rarely, if ever, cause TEN.

It appears that most drugs that cause maculopapular rashes form reactive metabolites, but it is hard to demonstrate that this is an essential part of the mechanism because this type of rash is not mediated by antibodies with an easily determined specificity. It appears that these rashes are mediated by CD4⁺ T cells [151]. This could explain why they are usually mild because CD4 interacts with major histocompatibility complex (MHC)-II, which is not present on most cells, and therefore, most cells would escape significant damage. Specifically, MHC-II is not normally expressed on keratinocytes, the major component of the epidermis; however, inflammation can result in the induction of MHC-II expression on keratinocytes and this could be part of the mechanism of these rashes [160].

12.4.2.3 Stevens–Johnson Syndrome/Toxic Epidermal Necrolysis (TEN). It appears that TEN and Stevens–Johnson syndrome share a very similar mechanism, but TEN is more severe and, by definition, involves more than 30% of the total skin area [161]. A classic feature of TEN is Nikolsky sign, where the application of lateral pressure to the skin results in its detachment. As indicated above, drugs that cause TEN, such as sulfonamides, allopurinol, carbamazepine, and phenytoin, more frequently cause mild maculopapular rashes. A major difference in the mechanism appears to be that TEN is mediated by CD8⁺ cytotoxic T cells [111,151]. This results in a more severe rash because CD8 binds to MHC-I, which is present on all nucleated cells, including keratinocytes, and therefore, the immune response can cause extensive damage to the skin. As with other IDRs, the drugs involved, with the possible exception of allopurinol, form reactive metabolites, but the mechanistic role of reactive metabolites remains to be determined.

12.4.2.4 Generalized Hypersensitivity Reaction/Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS). As the name implies, DRESS (drug reaction with eosinophilia and systemic symptoms) is a systemic immune-mediated reaction that is virtually always associated with a rash, but it also includes various other organs in the body and is usually associated with fever and eosinophilia [162,163]. This syndrome can be caused by many of the same drugs that cause TEN, such as carbamazepine, sulfonamide antibiotics, and allopurinol. However, the mechanism of this immune reaction appears to be fundamentally different from that of TEN because in Han Chinese, carbamazepine-induced TEN is strongly associated with the MHC-I gene HLA B5701, but this is not a risk factor for DRESS [164]. There is relatively new evidence that this syndrome involves reactivation of viruses by the drug, and this is discussed further in Section 12.5.1.4.

12.4.3 Idiosyncratic Drug-Induced Liver Injury (DILI)

Drug-induced liver injury (DILI) is the most common reason for removal of a drug from the market, and evidence of DILI during clinical trials can prevent a drug candidate from being approved [165]. Mild liver injury may be even more common than drug-induced skin rashes, but the liver is not visible, and so if the injury is asymptomatic, it is unlikely to be detected. It is likely that the reason that the liver is so commonly the target of IDRs is because it is the site of most drug metabolism and reactive metabolite formation. In fact, an immune response in the liver usually results in immune tolerance, and unlike skin transplants [166], immune rejection of liver transplants is relatively easy to prevent.

The involvement of reactive metabolites in the pathogenesis of most DILI is widely accepted [10,167]. However, this is difficult to definitively demonstrate, and there are probably cases that do not involve a reactive metabolite. The best example is probably ximelagatran, which does not appear to form a reactive metabolite. This drug was a promising anticoagulant, but it had to be withdrawn from the market because of an unacceptable risk of liver failure. It is a peptidomimetic drug and appears to bind reversibly to specific MHC-II molecules. Furthermore, the presence of these MHC-II molecules (DRB1*07 and DQA1*02) is a strong risk factor for ximelagatran-induced liver failure [168]. Pyrazinamide is also associated with a relatively high incidence of liver failure [169], and yet, it is a simple molecule with no evidence of a reactive metabolite.

The involvement of the immune system in the mechanism of DILI is more controversial. In some cases, such as DILI caused by halothane, tienilic acid, and dihydralazine, the DILI is associated with the presence of antidrug and/or autoantibodies against the P450 that formed the reactive metabolite of the drug [170]. This is taken by most people as evidence that DILI is immune mediated. However, it is unlikely that these antibodies actually mediate the liver damage. Most reactive metabolites of drugs that are associated with DILI are quite reactive and bind mostly to intracellular antigens. The resulting modified protein will be presented on the surface of hepatocytes in the context of MHC-I. Therefore, liver damage is more likely to be cell mediated, in particular, CD8⁺ cell mediated because CD8 binds to MHC-I. However, immune responses rarely produce only a cellular or an antibody response, and the antibody response may represent more an indication that the immune system has been activated rather than an indication of what arm of the immune system is involved in causing liver damage.

However, antibodies have not been detected in most cases of DILI, although to be fair, in most cases, it is likely that no one has looked for antidrug antibodies because the required ELISA reagents would have to be synthesized. Hepatotoxicity that is not associated with antibodies and other evidence of an allergic reaction such as fever and rash has been classified by some as metabolic idiosyncrasy [14]. One may not consider the absence of allergic symptoms to be significant evidence against an immune mechanism, and there are no cases in which a polymorphism in drug metabolism is sufficient to explain the idiosyncratic nature of idiosyncratic DILI [3]. Some DILIs are not associated with immune memory, that is, the onset of clinical symptoms of liver injury does not occur more rapidly on rechallenge of a patient who has previously experienced DILI to a specific drug. This represents stronger evidence against an immune mechanism; however, there are many immune-mediated reactions that are not associated with immune memory.

As mentioned above, the response to the same drug can vary from patient to patient. In one early report of isoniazid-induced DILI, one patient who was rechallenged developed fever within 4 h and shortly after the alanine aminotransferase (ALT) had increased more than 10-fold. In contrast, another patient with a history of isoniazid-induced DILI was treated with isoniazid for a month before there was an increase in ALT [89]. In many patients, isoniazid is stopped when there is a significant increase in ALT, but when they are later rechallenged, there is no increase in ALT, especially if the starting dose is lowered. It is also the case with ximelagatran that rechallenge of patients who had developed DILI on the drug usually did not lead to recurrence, even though ximelagatran appears to be immune mediated based on its association with specific HLA (human leukocyte antigen) genotypes (DRB1*07 and DQA*02) [168]. It is also provocative that there were cases of ximelagatran-induced DILI that did not occur until about a month after the drug was stopped [171]. It is hard to understand how this could be an antidrug immune response; it is more consistent with a drug-induced autoimmune reaction. There are other examples of IDRs starting after the drug has been stopped, as discussed below.

Some drugs such as minocycline, nitrofurantoin, and α -methyldopa can cause DILI with clear markers of an autoimmune reaction [15]. The cases of DILI that are associated with autoantibodies usually have a longer delay—often more than a year between starting the drug and the onset of liver injury. Drugs that cause autoimmune liver damage can also cause the more typical type of idiosyncratic DILI with a time to onset of about a month. Although one of the characteristics that has been used as evidence that DILI is not immune mediated is a long delay between starting the drug and the onset of injury, for example, troglitazone-induced DILI, it is possible that this is actually because the reaction has an autoimmune component even if it is not associated with the characteristic autoantibodies typical of autoimmune hepatitis: antinuclear and anti-smooth-muscle antibodies for type I autoimmune hepatitis and antiliver/antikidney microsome-I antibodies for type II autoimmune hepatitis [15].

12.4.4 Hematologic Idiosyncratic Drug Reactions

Drugs can affect any of the formed elements of the blood, either by damage to precursors in the bone marrow or by peripheral destruction of cells. The most common disorders are anemia in which the red blood cell count is decreased, thrombocytopenia in which the platelet count is decreased, agranulocytosis in which the neutrophil count is decreased, and aplastic anemia in which all three of these cells are decreased.

12.4.4.1 Anemia. The classic drug associated with idiosyncratic anemia is α -methyldopa, which causes an antibody-mediated autoimmune hemolytic anemia [172]. It is clearly immune mediated because it is associated with anti-red-cell antibodies that cause hemolysis, but the antibodies are not drug dependent, that is, they cause hemolysis in the absence of the drug [173]. It is not clear how α -methyldopa induces this autoimmune response, but being a catechol, it can form an *o*-quinone reactive metabolite, and it can also cause a lupus-like generalized autoimmune syndrome [174] and idiosyncratic liver toxicity that can have an autoimmune component [175]. At present, the most common cause of idiosyncratic drug-induced hemolytic anemia is the third-generation cephalosporins, and most of the drugs associated with hemolytic anemia are either chemically reactive or form reactive

metabolites. Some drugs, such as α -methyldopa, are mediated by autoantibodies, and others are mediated by drug-dependent antibodies [176]. The most common hypothesis of how these antibodies are induced is the hapten hypothesis, although a more recent hypothesis is that the drug (or reactive metabolite) alters the red cell membrane resulting in binding of other proteins to the altered membrane [176].

Another type of anemia is pure red cell aplasia, which reflects absent or dysfunctional red cell precursors. One such example is caused by erythropoietin treatment, which can induce antibodies against erythropoietin, a factor required for red cell development. This appears to be due to denaturation of the protein because the incidence of pure red cell aplasia is very dependent on the formulation. Specifically, the incidence increased when human serum albumin was removed from the erythropoietin formulation [177]. Pure red cell aplasia can also be caused by drugs such as procainamide and isoniazid, which can also induce other autoimmune syndromes [21,91].

12.4.4.2 Thrombocytopenia. The most common cause of idiosyncratic immune-mediated thrombocytopenia is heparin, which can induce the formation of antibodies against the complex of heparin and platelet factor 4, leading to platelet aggregation and consumption of the platelets [178]. Even though this IDR is mediated by antibodies, there is no immune memory, and if a patient with a history of heparin-induced thrombocytopenia is rechallenged after the antibodies have cleared from the blood, there is usually no recurrence, and if thrombocytopenia recurs, it has the same time course as in a naive patient [179].

There appears to be many mechanisms by which other drugs can cause thrombocytopenia [180]. Drugs such as penicillin can act as haptens and induce drug-dependent antibodies that lead to thrombocytopenia. Quinine causes thrombocytopenia that appears to be mediated by antibodies that bind to the drug and form immune complexes that then bind to platelets leading to their destruction as an “innocent bystander.” This appears to involve antibodies that are naturally weakly autoreactive with epitopes on the platelet membrane and bind more strongly after binding to the drug. Drugs such as procainamide, penicillamine, and gold salts can also induce the formation of autoantibodies that result in thrombocytopenia [181]. Another interesting mechanism involves tirofiban and eptifibatide, which cause an immediate destruction of platelets because of naturally occurring antibodies that appear to recognize a drug-induced conformational change in the membrane protein GPIIb-IIIa [182]. Abciximab, an antibody against GPIIb-IIIa, can also cause an immediate onset of thrombocytopenia because of naturally occurring antibodies that recognize the modified protein [183]. It can also cause thrombocytopenia that begins six days after abciximab treatment has been stopped, which is mediated by antibodies against drug-coated platelets that remain in the circulation [184].

12.4.4.3 Agranulocytosis. A lack of granulocytes is referred to as *agranulocytosis*, and it is usually defined as a peripheral neutrophil count of <500 neutrophils/ μL [185]. Neutrophils are a common target for cytotoxic drugs used to treat cancer because the very rapid turnover of these cells makes them especially susceptible to agents that damage DNA; agranulocytosis caused by cytotoxic drugs is not idiosyncratic. Many drugs can cause idiosyncratic agranulocytosis [186].

If idiosyncratic drug-induced agranulocytosis is caused by reactive metabolites, it is likely that the enzyme involved is myeloperoxidase, which is the major oxidative

enzyme in neutrophils. We and others have shown that most of the drugs that are associated with a relatively high incidence of idiosyncratic agranulocytosis are oxidized to reactive metabolites by myeloperoxidase. Such drugs include clozapine, aminopyrine, procainamide, propylthiouracil, amodiaquine, dapsone, and vesnarinone [63,70,101,154,187–189].

12.4.4.4 Aplastic Anemia. The diagnosis of aplastic anemia cannot be confidently made without a bone marrow biopsy that shows a marked decrease in the cellularity of the bone marrow with replacement of normal hematopoietic cells by fat cells [190]. This leads to a lack of neutrophils, platelets, and red blood cells, which is eventually fatal if not reversed. The cause of most aplastic anemia is unknown (idiopathic). It sometimes follows a viral infection such as viral hepatitis, but about 10% is caused by drugs. There is strong evidence that aplastic anemia, both idiopathic and drug induced, is immune mediated. In particular, it appears to be mediated by cytotoxic T cells that are characterized by the production of interferon- γ [191]. As a result, both idiopathic and idiosyncratic aplastic anemia usually respond to immunosuppression. It has been noted that chloramphenicol-induced aplastic anemia often occurs well after the drug is stopped, sometimes more than two months after, and the longer the delay, the more severe the aplastic anemia is likely to be [82]. This is consistent with an autoimmune mechanism, but there is no direct evidence for this hypothesis. There is some overlap in the drugs that cause agranulocytosis and aplastic anemia, but there are also significant differences [154]. A major difference is that the target of aplastic anemia is a very early cell close to the stem cell and therefore recovery is much slower than for agranulocytosis, which involves much more differentiated cells, and in some cases, it appears that only mature neutrophils are destroyed.

12.5 MAJOR HYPOTHESES OF IDIOSYNCRATIC DRUG REACTIONS

The mechanisms of IDRs are open to debate because, with a few exceptions such as penicillin-induced anaphylaxis, the evidence is circumstantial rather than definitive. Prospective mechanistic studies in humans are virtually impossible, and there is a paucity of animal models. In addition, most of the animal models involve acute toxicity and probably do not involve the same mechanism as the analogous IDR that occurs in humans, given the low incidence and especially the delay in onset in man. There are several working hypotheses (discussed in detail later), but without a battery of valid animal models, testing these hypotheses represents a major challenge. An essential test of any model or hypothesis is whether it fits the characteristics of clinical IDRs.

12.5.1 Immune-Mediated Mechanisms

The idiosyncratic nature and delay between starting a drug and the onset of the adverse reaction described earlier suggest that most IDRs are immune mediated. By definition, drug-induced autoimmunity must be immune mediated. There is ample evidence that most drug-induced skin rashes are immune mediated. Some hematological IDRs are clearly mediated by antibodies. It appears that most drug-induced aplastic anemia is immune mediated because it usually responds to immunosuppression as discussed earlier. Aminopyrine-induced agranulocytosis appears to be mediated by drug-dependent

antineutrophil antibodies [192]. In contrast, some drug-induced agranulocytosis has characteristics that suggest that it is not immune mediated. Specifically, phenothiazine-induced agranulocytosis is said to result from toxic suppression of bone marrow rather than being immune mediated [193]. Clozapine-induced agranulocytosis also does not usually recur rapidly on rechallenge, and this lack of immune “memory” also suggests that it might not be immune mediated [194]. However, these characteristics are consistent with an immune mechanism because there are other IDRs with similar characteristics that are clearly immune mediated, as described earlier. The most controversial issue is whether cases of idiosyncratic liver toxicity that are not associated with other evidence of an immune response, for example, fever, rash, and antibodies, are immune mediated. In fact, even the evidence that the liver injury associated with drugs such as halothane, in which there does appear to be immune memory and there are antidrug antibodies, is not conclusive, and not everyone believes that halothane-induced liver failure is immune mediated.

It is likely that the vast majority of IDRs are immune mediated. Certainly not all, or even most, immune-mediated reactions are associated with features such as fever and rash. In addition, there are several examples of clearly immune-mediated reactions that do not exhibit immune memory [3]. One possible reason for the lack of immune memory is that the immune response has an autoimmune component and this results in deletion or silencing of the memory T cells. However, until better evidence for an immune mechanism for some IDRs is obtained, this still must be considered a hypothesis open to debate.

The following are the major mechanistic hypotheses for immune-mediated IDRs.

12.5.1.1 Hapten Hypothesis. The hapten hypothesis is based on very old experiments that found that small molecules did not induce an immune response unless they were able to covalently bind to macromolecules [195]. A small molecule that is not immunogenic unless it is bound to a macromolecule is referred to as a *hapten*. This became part of the self–nonself view of what induced an immune response, in which the immune system differentiates between self and nonself or foreign at an early age and only responds to nonself molecules [196]. In this case, the covalent binding of small molecules to proteins results in them becoming “foreign,” and this leads to an immune response (Fig. 12.1). Presumably, the reason why covalent binding of the hapten is required is for antigens (in this case, drug-modified protein) to be presented to T cells, they must first be processed. Processing essentially involves hydrolysis of the proteins to peptides, and if the interaction of the drug with the protein was readily reversible, it would not survive processing. There is compelling evidence that the hapten hypothesis is correct for some IDRs; specifically, for IDRs such as penicillin-induced allergic reactions that are mediated by antibodies against drug-modified proteins, as discussed in Section 12.4.2.1. However, that does not mean that all IDRs are mediated by an immune response to drug-modified proteins.

There are many examples in which drugs induce autoantibodies rather than antidrug antibodies; this does not fit the simple hapten hypothesis. There are also many examples, such as halothane-induced hepatitis, that are associated with both antibodies against drug-modified proteins and native proteins [197]. Two possible mechanisms related to the hapten hypothesis by which covalent binding of a reactive metabolite to proteins could induce autoantibodies are epitope spreading and presentation of cryptic peptides. When an immune response is induced against drug-modified proteins, the

Figure 12.1 Hapten hypothesis. A drug, or more commonly a reactive metabolite of the drug, binds to protein and this makes the protein foreign. The modified protein is taken up by anti-gen-presenting cells (APCs), processed to smaller peptides, and these drug-modified peptides are presented in the context of MHC-II to T cells. TCR, T-cell receptor. (See color insert.)

epitope recognized will be different for different T cells, with some recognizing mostly the drug and others, mostly the peptide portion of the modified protein. As the immune response progresses, it may spread to recognize only the native peptide [198,199]. In contrast, the concept of cryptic peptides involves a change in the way the drug-modified protein is processed because of the change in its structure. If this leads to a change in the major site of hydrolysis of the peptide, the immune system may be exposed to peptides it has not seen before, at least not in high concentrations, and therefore, they may be recognized as foreign [200].

12.5.1.2 Danger Hypothesis. In recent years, it has become apparent that the self–nonself picture of the immune response is incomplete because not all autoreactive T cells are deleted, and there is no difference in the manner in which self and nonself antigens are presented to T cells. It was also found that at least two signals were required in order to activate T cells [201]. Signal 1 refers to the recognition of the processed antigen by the T-cell receptor. A second signal, referred to as *signal 2*, is also required for activation. This second signal consists of costimulation of T cells by interaction of various molecules on the antigen-presenting cell, such as B7 (otherwise known as *CD80/86*), with receptors on the T cell, such as CD28. The level of molecules such as CD80/86 on antigen-presenting cells is usually low unless the cell is activated, and therefore, activation of antigen-presenting cells is required to induce an immune response. There are various receptors on antigen-presenting cells called *toll-like receptors* that recognize molecules on pathogens, and binding of these molecules to toll-like receptors leads to activation of the cells [202]. However,

Figure 12.2 Danger hypothesis. A drug or reactive metabolite not only modifies protein but also causes cell damage. This damage causes the damaged cells to release danger signals such as heat shock proteins (HSPs), which in turn activate antigen-presenting cells leading to the upregulation of costimulatory molecules on antigen-presenting cells. This costimulation of T cells represents signal 2 where the recognition of the modified peptides by the T-cell receptor represents signal 1. The presence of both signal 1 and signal 2 leads to helper-T-cell activation, while signal 1 in the absence of signal 2 leads to immune tolerance. (See color insert.)

Matzinger suggested that differentiation between self and nonself was difficult and unnecessary. She suggested that unless something represented a danger to an organism, it could ignore it [203]. Furthermore, she suggested that it is the damaged tissue that determines not only if there will be an immune response but also the nature of that response [204]. It was also discovered that some of the “danger signals” that were produced by damaged tissue bind to the toll-like receptors that are activated by pathogens [205]. Reactive metabolites could cause cell damage that leads to the release of danger signals and upregulation of costimulatory molecules such as B7, thus producing signal 2 (Fig. 12.2). Reactive metabolites might also induce an autoimmune reaction by inducing cell damage that leads to a generalized activation of the immune system.

If this hypothesis is correct, it could explain why some drugs that covalently bind to proteins are not associated with a significant incidence of IDRs; if the reactive metabolite does not cause cell damage and the generation of a consequent danger signal, it would not induce an immune response. Alternatively, some other factors such as an infection could produce a danger signal and this could be a risk factor for an IDR. There are some cases where an infection or surgery appears to be a risk factor for an IDR [206]. However, this is not always the case, and it is important to remember that not all infections have the same effect and the effect of acute infections

on the immune system are quite different than chronic infections. The danger and hapten hypotheses are not mutually exclusive, and both protein modification (hapten hypothesis) and cell damage (danger hypothesis) may be required to induce the immune responses that lead to many IDRs as illustrated in Fig. 12.2. The danger hypothesis is attractive and it is likely to be part of the picture; however, it is difficult to rigorously test.

12.5.1.3 *p-I Hypothesis.* Pichler found that clones of T cells from patients with a history of sulfamethoxazole-induced IDRs proliferated in the absence of metabolism of the drug [207]. He also found similar effects with some other drugs. From this, he reasoned that drugs must be able to generate an immune response by binding reversibly to the antigen-presenting cell MHC/T-cell-receptor complex much like the p-I of a drug binding to its receptor. This led to the name p-I hypothesis [208]. In the case of sulfamethoxazole, this seems strange because sulfamethoxazole is a primary aromatic amine and virtually all primary aromatic amines given at a significant dose are associated with a significant incidence of IDRs, presumably because they are readily metabolized to reactive metabolites [209]. The unstated assumption in the p-I hypothesis is that the T cells are responding to the molecule that initially induced the immune response. We have found that this basic assumption is incorrect. Specifically, in a model of immune-mediated nevirapine-induced skin rash, even though the drug requires hydroxylation in order to induce a skin rash, T cells from animals with nevirapine-induced skin rash produced much more cytokines when stimulated with the parent drug than the hydroxylated metabolite. In fact, even if the skin rash was induced by treatment with the hydroxylated metabolite rather than the parent drug and the animals had never been exposed to the parent drug, the T cells responded much more to the parent drug [157]. Even though this is an animal model, it provides definitive evidence that there can be differences between what stimulates an immune response and what T cells respond to later in an immune response. In addition, the use of clones in Pichler's experiments, which were selected based on the growth in the presence of drug rather than primary lymphocytes, may select for cells that respond to the parent drug. In fact, a more recent study found that lymphocytes from patients with IDRs to sulfamethoxazole responded much better to the nitroso metabolite than to the parent drug [210]. There may be some examples such as ximelagatran, which does not appear to form a reactive metabolite, where the drug induces an immune response through the p-I mechanism. In fact, ximelagatran, which looks like a peptide, was found to bind directly to DRB1*07 and DQA1*02, and these genotypes are a significant risk factor for ximelagatran-induced liver toxicity [168]. However, it is unlikely that this is a common mechanism for the induction of an IDR.

12.5.1.4 *Viral Reactivation.* It was observed many years ago that patients with mononucleosis who were treated with ampicillin had a very high incidence of skin rash [211]. More recently, it was found that many cases of DRESS are associated with reactivation of a virus, most commonly, a herpes virus [212,213]. It is not totally clear exactly what role the virus and the drug play in these IDRs, although it seems likely that the drug somehow decreases the immune response, thereby allowing reactivation of the virus, and the virus could act as a danger signal to help produce an immune response against the drug.

12.5.1.5 Unfolded Protein Response. A large number of protein molecules are synthesized every second, and they have to be folded and moved to where they are needed. When there is an accumulation of abnormally folded proteins, there is a specific response referred to as the *unfolded protein response* [214]. This response can result in inflammation [215]. There are many things that can lead to the accumulation of unfolded proteins, but if the reactive metabolite of a drug modifies a protein, it could interfere with the normal folding of a protein and this could lead to an immune response. However, there are no clear examples in which this has led to an IDR. To some degree, this is a variant of the danger hypothesis.

12.5.1.6 Epigenetic Effects Such as Inhibition of DNA Methylation. A major mechanism by which gene expression is controlled is epigenetic [216]. Methylation of the 5-position of cytosine in DNA inhibits gene expression, and most DNA cytosine is methylated. A decrease in DNA methylation in B cells leads to their activation, and autoimmune diseases such as lupus are associated with decreased DNA methylation [217]. Some drugs such as procainamide and hydralazine can inhibit DNA methylation, and these drugs are associated with the induction of a lupus-like autoimmune syndrome, as discussed in Section 12.4.1.1 [147]. This mechanism could also contribute to other types of IDRs; however, there are no good examples where epigenetic effects have been shown to result in an IDR other than autoimmunity.

12.5.1.7 Direct Activation of Antigen-Presenting Cells. As discussed in Section 12.5.1.2, a second signal resulting from the activation of antigen-presenting cells is required for the induction of an immune response. This activation could be accomplished by danger signals produced by damaged tissue, but it is possible that a drug or reactive metabolite could directly activate antigen-presenting cells. We found that drugs that react with aldehydes such as penicillamine, hydralazine, and isoniazid directly activate antigen-presenting cells, apparently by reacting with signaling molecules on these cells that have reactive carbonyl groups [148,149]. These drugs can cause autoimmune reactions. Antigen-presenting cells also possess myeloperoxidase that can generate reactive metabolites that have the potential to activate these cells [218]. One likely example is the reactive nitroso metabolite of sulfamethoxazole, which is formed by myeloperoxidase and can activate dendritic cells [153].

12.5.1.8 Disturbing Immune System Balance. Many new biological agents work by inhibition of various arms of the immune system. Paradoxically, these agents can result in an immune-mediated IDR, presumably by altering the balance of the immune system. The exact mechanism is unknown, but because virtually all biological agents that target the immune system can cause various forms of autoimmune reactions, even though their specific targets are different, simply altering the balance of various arms of the immune system appears to have the potential to cause autoimmunity. Other agents may act by a similar mechanism, but this is more difficult to demonstrate.

12.5.2 Non-Immune-Mediated Mechanisms

Although the characteristics of IDRs suggest that they are immune mediated, the evidence remains circumstantial, and at least some IDRs may not be immune mediated. The involvement of the immune system in idiosyncratic DILI is the most controversial.

12.5.2.1 Metabolic Idiosyncrasy. Zimmerman [14] classified DILI that was not associated with features of an immune response such as antidrug antibodies, fever, and rash as metabolic idiosyncrasy. In general, this classification has been accepted. Drugs that fit this category include isoniazid, ketoconazole, and troglitazone. On average, cases that fit this description occur later and are more severe. The explanation for toxicity associated with these drugs is that it is caused by polymorphisms in metabolism that lead to a difference in response. However, polymorphisms in the metabolism of isoniazid, specifically *N*-acetyltransferase 2 and Cyp 2E1, confer a slight increase in risk of liver toxicity [219], the increase in risk is much too small to explain the idiosyncratic nature of severe cases of isoniazid-induced liver toxicity. Such a mechanism also does not explain the delay between starting the drug and the onset of toxicity or the difficulty producing an animal model with characteristics similar to the idiosyncratic reaction that occurs in humans. In some cases, there is an amnestic response to drugs classified as metabolic idiosyncrasy, such as isoniazid, as mentioned in Section 12.4.3, and ketoconazole. In one case of ketoconazole-induced DILI, a patient developed hepatitis 60 days after starting ketoconazole, and 30 months later, she was inadvertently treated with ketoconazole and within 48 hours she again developed hepatitis. However, in many cases, there is no prompt recurrence on rechallenge [220]. When there is a very rapid response on rechallenge, it strongly supports an immune mechanism; when there is a lack of an amnestic response, it is consistent with an autoimmune reaction [15]. Although polymorphisms in drug metabolism undoubtedly represent a risk factor for some IDRs, it is likely a minor mechanism of IDRs per se.

12.5.2.2 Mitochondrial Toxicity. The hypothesis that many cases of idiosyncratic liver toxicity involve mitochondrial damage is currently receiving much attention. Mitochondria supply the cell with energy through the Krebs's cycle, oxidative phosphorylation, and fatty acid β -oxidation, which could all be potential targets of toxicity for drugs and their reactive metabolites. Mitochondria also control cell death via apoptosis/necrosis through the opening of the mitochondrial permeability transition pore and the release of cytochrome *c*. Mitochondria have their own genome, which is vulnerable to oxidative damage because of the lack of protective histones and its close proximity to the inner membrane, which is the major source of endogenous reactive oxygen species in a cell. In addition, lipophilic cationic drugs can accumulate in the mitochondrial matrix because of the negative membrane potential [221]. There are several copies of mitochondrial DNA (mtDNA) in each mitochondrion and there are hundreds of mitochondria in a hepatocyte; therefore, if a drug or its reactive metabolite caused damage to mtDNA, the cell could continue to function normally (also known as *functional reserve*) until the cumulative damage reached a certain threshold and this could explain the delayed onset of idiosyncratic liver toxicity [222].

Much of the evidence for mitochondrial injury being responsible for DILI comes from *in vitro* studies using high concentrations of drug; this is not credible on its own to support the hypothesis. For instance, Xu *et al.* studied over 300 compounds in human hepatocytes using fluorescent probes and found that many drugs that cause idiosyncratic liver toxicity caused a perturbation in a marker associated with mitochondrial function, while drugs that are not associated with liver toxicity usually did not [223]. However, the study used concentrations of drugs that were 100-fold the therapeutic $C_{\max}$ achieved in humans. This was justified by saying that the kinetics could be different in some people and that the concentration in the liver during absorption would be higher than

the blood concentration. However, if this were the mechanism of DILI, it should be possible to induce DILI in animals simply by giving higher doses of the drug. In addition, several drugs, such as isoniazid and flutamide, that have been proposed to cause DILI by injuring mitochondria were considered negative and nimesulide, which is also believed to cause DILI via mitochondrial damage, was considered positive because of a marker for reactive oxygen species, but it was negative with respect to the mitochondrial marker. Furthermore, some of the agents that appeared the most dangerous in the assay, such as hydrochlorothiazide, were considered “hits” because there have been reported cases of liver toxicity, but these drugs very rarely cause idiosyncratic liver toxicity and, thus, could be viewed as false positives.

Probably, the best *in vivo* model for mitochondrial involvement in idiosyncratic liver toxicity comes from studies using the Sod2 heterozygous (Sod2+/-) mice. Sod2 is the mitochondrial form of superoxide dismutase that detoxifies superoxide anions, which are generated by the electron transport chain as an inevitable side product. Therefore, mice deficient in this enzyme would be expected to have increased oxidative damage to their mtDNA and proteins. This might make them more susceptible to drug-induced mitochondrial toxicity; however, the results have been conflicting. In one of the first published studies, troglitazone caused an increase in markers of mitochondrial oxidative stress and an approximately twofold increase in ALT and hepatic necrosis in Sod2+/- mice, but not wild-type mice after four weeks of treatment [224]. But another study by Fujimoto *et al.* was not able to reproduce these results [225]. Specifically, plasma ALT increased in both the mutant and wild-type mice, and no hepatic necrosis was observed. This discrepancy in findings could be attributable to differences in the route of administration, solvent, or formulation. Ong used a crystalline form of troglitazone in Solutol-HS 15 (composed of polyglycol esters of 12-hydroxystearic acid and polyethylene glycol) and administered it intraperitoneally. In contrast, Fujimoto treated the mice orally with an amorphous coprecipitate of troglitazone in carboxymethylcellulose solution. Solutol-HS 15 has been found to be a weak inhibitor of CYP3A4 and could affect the metabolism of troglitazone, which is a CYP3A4 substrate [226]. In addition, Solutol-HS is a fatty acid analog, which has the potential to cause or potentiate mitochondrial damage analogous to valproic acid. Another study using Sod2+/- mice involved flutamide, where treatment for four weeks caused hepatic necrosis, a mild increase in ALT, and an increase in serum lactate in Sod2+/- mice but not in wild-type mice. Microarray analysis of gene expression showed that there was decreased expression of 12 of the 13 mitochondrial genes coding for subunits in the electron transport chain complexes and 7 of the 22 mitochondrial genes coding for mitochondrial tRNA (mtRNA), which suggests a selective damage to mtDNA. However, these changes in mtRNA levels occurred in the wild-type mice as well [227].

It is essential that any hypothesis be consistent with the clinical picture of idiosyncratic DILI. The histological finding of microvesicular steatosis that occurs in many cases of valproate-induced liver toxicity is quite strong evidence for mitochondrial involvement [228], and genetic defects affecting mitochondrial function are a risk factor for valproate-induced IDRs [229]. Other clinical evidence for mitochondrial involvement in DILI comes from electron microscopy findings of mitochondrial abnormalities (swelling and loss of cristae) in patients who developed liver toxicity with nucleoside reverse transcriptase inhibitors or fialuridine, which are believed to inhibit mtDNA replication because they are nucleoside analogs [230,231]. Nucleoside reverse transcriptase inhibitors are associated with increases in ALT; however, it is often difficult

to differentiate effects of the drug from those of the HIV or associated infections [232]. There are inherited mtDNA depletion syndromes that are also associated with steatosis and lactic acidosis that manifest in infants [233]. This type of toxicity is cumulative and delayed in onset as suggested by Boelsterli. However, steatosis and lactic acidosis are not typical of idiosyncratic liver toxicity. It is hard to understand how damage to mtDNA that is sufficient to cause severe DILI leading to liver failure would not also cause steatosis and/or lactic acidosis. It is also hard to understand how damage other than damage to mtDNA would be delayed and cumulative because damage to proteins with a short half-life should occur more rapidly than is typical for idiosyncratic DILI. The most serious cases of DILI are usually those that progress after the drug is stopped, and that is consistent with a mechanism involving DNA damage, which is usually cumulative. However, the same drugs that are responsible for such severe reactions much more commonly cause mild DILI that resolves despite continued treatment with the drug [234]. Such a picture is not consistent with a mechanism that involves mtDNA damage. It is intriguing to note that two studies have found an association between mitochondrial Sod polymorphisms and the risk of idiosyncratic DILI [235,236]. In one case, the association was with hepatocellular damage in patients being treated with antituberculosis drugs, and in the other study, the association was with a cholestatic/mixed injury type of DILI caused by a variety of other drugs. In both cases, the increased risk was associated with the genotype that had the higher mitochondrial Sod concentration. This is difficult to reconcile with the mitochondrial Sod heterozygote mouse model.

In summary, there is strong evidence that the primary mechanism of DILI for a few drugs involves mitochondrial damage. This DILI is characterized by steatosis and/or lactic acidosis. It seems unlikely that this is the mechanism for most idiosyncratic DILI. It is possible that mitochondrial toxicity requires a specific genetic defect to become manifest, but if that is true, then *in vitro* assays using random cells should not work, and if a genetic defect is not required, it should be possible to reproduce idiosyncratic DILI in animals using high doses. All drugs developed in the last several decades have been tested in animals at high doses that result in blood levels higher than the therapeutic concentrations in humans. In general, these conditions did not result in DILI even for those drugs that were later found to cause an unacceptable risk of idiosyncratic liver failure. Therefore, it seems unlikely that simple mitochondrial injury is sufficient to explain most idiosyncratic DILI. However, mitochondria are very important for normal cell function, and it is quite plausible that milder mitochondrial damage that is not sufficient to cause steatosis or lactic acidosis could produce cell stress and a danger signal that stimulates an immune response leading to DILI. Such a hypothesis is consistent with the characteristics of idiosyncratic DILI, and therefore, mitochondrial damage may be an important part of the overall mechanism of DILI. If this hypothesis is correct, it could still form the basis to screen drug candidates for their potential to cause DILI, although to date, such screening methods have not proven to be very accurate.

12.5.2.3 Inflammagen Hypothesis. Roth has proposed that most idiosyncratic DILI are not mediated by the immune system, at least not the adaptive immune system [237]. He found that the combination of lipopolysaccharide (LPS) and drugs such as ranitidine caused acute liver injury [238]. There are many issues with this hypothesis. First, the observed toxicity is acute and does not fit the delayed-onset characteristic of

idiosyncratic liver injury. Although it was reasoned that the usual delay in idiosyncratic liver injury could be due to the chance occurrence of an inflammatory stimulus, this would predict a random time to onset. It would not predict the observation that with the exception of a very limited number of drugs, such as telithromycin [239], idiosyncratic response virtually never occurs immediately on first exposure, or with the exception of a few other drugs, especially drugs that cause autoimmune hepatotoxicity, rarely occurs after six months of treatment [3]. The histology in this model, which is dominated by neutrophils [238], also does not fit the typical histology observed with idiosyncratic liver toxicity, which is usually dominated by lymphocytes and is similar to that of viral hepatitis [14]. Although LPS can cause acute hepatic damage, the response to LPS is rapidly downregulated [240]. Specifically, previous exposure to other toll-like receptor agonists prevents LPS hepatotoxicity [241]. The most serious cases of idiosyncratic liver toxicity are those in which the damage progresses even after the drug is stopped, but this model has never been extended in time to determine the natural course of the injury. On the basis of the danger hypothesis, we have tried to use LPS and other toll-like receptor agonists along with drugs such as isoniazid and nevirapine to produce a model of idiosyncratic liver injury, but without success (Utrecht JP, unpublished observations). One of the problems is that such inflammatory stimuli rapidly downregulate cytochrome P450 synthesis [242], which markedly decreases reactive metabolite formation. The inflammagen model also would not be of use in predicting the risk of idiosyncratic liver toxicity because it is positive with ranitidine, which is a safe over-the-counter drug, but negative for isoniazid, which is associated with the highest incidence of idiosyncratic liver toxicity of any commonly used drug.

12.6 IMPLICATIONS OF REACTIVE METABOLITES FOR THE MECHANISMS OF IDIOSYNCRATIC DRUG REACTIONS

As stated in Section 12.3, there is a large amount of circumstantial evidence that chemically reactive metabolites of drugs are involved in mechanism of most idiosyncratic drug reactions. The question becomes exactly what role do they play and what types of reactive metabolites are most likely to cause IDRs.

12.6.1 Implications of Reactive Metabolites for Specific Mechanistic Hypotheses

The requirement for reactive metabolites is consistent with the hapten hypothesis, which requires covalent modification of macromolecules in order to induce an immune response. This also fits the observation that many IDRs are associated with antibodies against drug-modified proteins or even autoantibodies, which could be induced because of epitope spreading or the formation of cryptic peptides as discussed in Section 12.5.1.1.

The requirement for the formation of reactive metabolites is also consistent with the danger hypothesis as discussed in Section 12.5.1.2. There are many ways by which reactive metabolites could cause cell stress resulting in the release of danger signals including mitochondrial injury. We have used microarray studies to search for evidence of danger signals generated by drugs that cause a relatively high incidence of IDRs. Although we and others have found changes in gene expression that could represent a danger signal, we have not observed any consistent patterns that could be used to screen

drug candidates for the risk that they would cause IDRs [243–246]. Furthermore, it is very difficult to determine if the changes that were observed actually represent danger signals.

The p-I hypothesis specifically does not require a reactive metabolite, although a reversible interaction between the drug and the MHC/T-cell-receptor complex, the basis for the p-I hypothesis, could produce signal 1 and a reactive metabolite could produce signal 2 consistent with the danger hypothesis. Therefore, the p-I hypothesis does not preclude the involvement of a reactive metabolite.

It is not clear what the implications of reactive metabolites are for the viral reactivation hypothesis, although it is possible that a reactive metabolite could be responsible for inhibition of the immune system and allow viral reactivation. A requirement for reactive metabolites is consistent with the unfolded protein response because it is presumably covalent binding of the reactive metabolite that interferes with normal protein folding. A reactive metabolite is not required for epigenetic effects because it appears that it is the parent drug in the case of procainamide and hydralazine that inhibits DNA methylation. Direct activation of antigen-presenting cells does not absolutely require a reactive metabolite, but certainly a reactive metabolite could be responsible for activation, and in the case of penicillamine, hydralazine, and isoniazid, it appears to be direct binding of the parent drug to specific active carbonyl groups on the antigen-presenting cells that is responsible for the activation, as discussed in Section 12.5.1.7. It is very unlikely that biological agents such as antibodies form reactive metabolites, so the IDRs associated with these agents do not involve reactive metabolites. With the nonimmune hypotheses there is no specific requirement for a reactive metabolite, but any of the three proposed mechanisms could involve a reactive metabolite.

12.6.2 Different Types of Reactive Metabolites are Associated with Different IDR Risks

There appears to be a correlation between the amount of covalent binding and the risk that a drug will cause idiosyncratic hepatotoxicity as discussed in Section 12.3; however, it is not possible to determine exactly how good this correlation is because it always involves extrapolation from *in vitro* to *in vivo* or from animals to humans. It is simply not feasible to give a person a large dose of radiolabeled drug and then do a liver biopsy to determine the extent of covalent binding. Furthermore, it is clear that different drugs are associated with a different spectrum of IDRs; therefore, assuming that reactive metabolites are responsible, different reactive metabolites must have different effects.

One important characteristic of a reactive metabolite is the location of formation; generally, metabolite reactivity is inversely proportional to the distance the agent is capable of traveling through cells and tissues. However, there are a few reactive species such as β -lactams and acyl glucuronides that circulate freely. This means that they have the potential to cause IDRs anywhere in the body. In addition, they can also react with extracellular proteins. This is in contrast to metabolites whose reactivity compels them to react with the closest target molecule, which is often the enzyme that formed them. Indeed, such reactive metabolites only bind to intracellular proteins. The significance of this difference is that intracellular proteins are presented in the context of MHC-I, which usually results in a cell-mediated immune response. In contrast, extracellular antigens can be presented in the context of MHC-II and lead to an antibody-mediated

response. A good example of this difference was demonstrated by experiments by Hopkins *et al.* in which agents that predominately reacted with serum proteins induced a type 2 cytokine response, while those that reacted with intracellular proteins produced a type 1 cytokine response [247]. It is interesting to note that in most cases the highest degree of covalent binding is in the liver even if the IDR involves a different organ. For example, the covalent binding of clozapine and nevirapine is higher in the liver than in the bone marrow and skin, respectively; however, the most common IDR associated with clozapine is agranulocytosis and that for nevirapine is skin rash (Utrecht JP, unpublished observations). Reactive metabolites formed by the myeloperoxidase system in antigen-presenting cells have obvious implications for immune-mediated reactions. It is unclear whether the skin has sufficient P450 activity to bioactivate drugs that cause skin rashes.

Another obvious important characteristic of a reactive metabolite is its chemical reactivity. As mentioned above, if a reactive metabolite is very reactive, it is likely to bind to the enzyme that formed it. In addition, some reactive metabolites are “hard” and selectively react with “hard” nucleophiles such as lysine amino groups, while others are “soft” and selectively react with “soft” nucleophiles, especially the thiol group of cysteine. The terms *soft* and *hard* refer to the degree to which the electrophilic or nucleophilic site is concentrated (hard) or diffuse (soft). However, there appears to be many additional parameters that determine what proteins a reactive metabolite will react with. For example, we compared the pattern of protein binding for three drugs that are oxidized to reactive metabolites by the myeloperoxidase system of neutrophils and cause agranulocytosis. In particular, clozapine and vesnarinone are oxidized to soft electrophiles that selectively bind to thiols. Yet when incubated with activated neutrophils, the pattern of proteins to which they bind was very different [248]. The binding of procainamide was also different, but, although procainamide also forms a soft electrophile, its chemical reactivity is a bit different. Hanzlik has compiled a database of the proteins that are covalently modified by reactive metabolites of drugs and other xenobiotics, and the diversity and difference between different reactive metabolites is surprising [249]. This suggests that physical characteristics such as how different chemical species interact noncovalently with proteins play an important role in determining which proteins are the major targets of binding. It is not surprising that binding to some proteins would be more likely to cause IDRs than others, but it is not clear what the most important protein targets might be with respect to causing IDRs. It is plausible that quinone-type reactive metabolites are the most common type of reactive metabolite that is associated with IDRs, and some types such as acyl glucuronides are much less likely to cause IDRs.

12.7 CLASSIFICATION OF DRUGS BASED ON THEIR IDR PATTERN

There appears to be patterns of the type of IDRs that different drugs cause. Part of the pattern is likely based on the duration of drug therapy. Specifically, halothane is used acutely for anesthesia and therefore is unlikely to cause autoimmunity, which usually requires a prolonged period of treatment. In some cases, the pattern may not be completely known because the drug was withdrawn before large numbers of patients were treated.

12.7.1 Drugs Causing Multiple Types of IDRs, Often Including Autoimmunity

There are many drugs that can cause multiple types of IDRs (Table 12.1). These tend to be older drugs that usually are known to form reactive metabolites. These drugs include aromatic amines such as procainamide, sulfamethoxazole, aminogluthethimide, and nomifensine; nitro compounds such as nitrofurantoin and chloramphenicol; hydrazines such as isoniazid and hydralazine; thiono sulfur compounds such as methimazole and propylthiouracil; and drugs that form quinone-type reactive metabolites such as indomethacin, minocycline, trimethoprim, and amodiaquine. Many drugs such as carbamazepine form several different types of reactive metabolites [108]. Yet even with drugs that are structurally similar, such as sulfamethoxazole and dapsone, the spectrum of IDRs varies from one drug to another and from one patient to another. It is almost certain that these are immune-mediated IDRs in which the structures to which the immune response is directed varies from one drug to another and from one patient to another. This variability is consistent with a mechanism in which the range of proteins modified by a reactive metabolite and the variability of the specificity of T-cell receptors (which are even different in identical twins) determines the variability of the IDR [15]. In one individual, the highest affinity T-cell receptor may recognize a drug-modified hepatic protein and lead to DILI, whereas in another individual, the highest affinity T-cell receptor may recognize a drug-modified skin protein or even a cryptic self peptide leading to a skin rash or an autoimmune reaction, respectively. If the mechanism were mediated by toxicity to a specific target such as mitochondria, it would be almost impossible to explain how a single drug could cause such a variety of IDRs.

12.7.2 Drugs in Which the Dominant IDR is DILI

There are some drugs that cause IDRs that are dominated by DILI (Table 12.2). Therefore, it is not possible to argue that the IDR caused by these drugs must be immune mediated based on this variability. In many cases, such as with halothane, it is likely that the reason that the toxicity is limited to the liver is because most of the reactive metabolite is formed in the liver and the reactive metabolite is too reactive to escape in significant concentrations. In some cases, such as with tolcapone, the drug may have been on the market for too short a time to detect other types of DILI. DILI caused by drugs such as halothane and tienilic acid appears to be immune mediated because it is associated with antidrug or autoantibodies and is associated with immune memory, that is, it occurs more rapidly on reexposure to the drug. In the case of some drugs such as ketoconazole, no antibodies have been described but there are cases demonstrating a rapid response on rechallenge, which strongly supports an immune mechanism as described above [220]. In the case of many drugs, we simply do not have rechallenge data. With drugs such as bromfenac and lumiracoxib, the drugs were withdrawn quickly, and given their structures, bromfenac is a primary aromatic amine and lumiracoxib is a close analog to diclofenac, it is likely that the mechanisms are similar to other drugs in Table 12.1 with similar structures. It is possible that the mechanism of DILI for some of the drugs in Table 12.2 involves a different mechanism that does not involve the immune system such as mitochondrial damage. However, the evidence for specific nonimmune mechanisms is weak, and such mechanisms do not fit the clinical characteristics of IDRs. It is likely that some IDRs involve a combination

TABLE 12.2 Drugs Primarily Associated with DILI

Drug	Structure	Reactive Metabolite	Idiosyncratic Reaction
Halothane		Acid chloride [250]	DILI [251]
Tolcapone		Nitro reduced to nitroso, hydroxylamine, and free radicals [252]	DILI [253]
Dantrolene		Nitro reduced to nitroso, hydroxylamine, and free radicals [252]	DILI [254] Pleurisy and pericarditis [255]

Nimesulide

Diiminoquinone [256]

DILI [257] **Hemolytic anemia** [258]
Generalized
pustulosis[259] Fixed
drug eruption [260]

Bromfenac

Aromatic amine oxidized
to hydroxylamine,
nitroso metabolites,
and *N*-chloramine (see
procainamide)

DILI [261] (quickly
withdrawn, given its
structure, it likely
would have caused
other IDRs)

Lumiracoxib

Iminoquinone (see
diclofenac)

DILI [262] (given the
structure, the pattern is
probably similar to
diclofenac but it was
withdrawn early)

(continued overleaf)

TABLE 12.2 (Continued)

Drug	Structure	Reactive Metabolite	Idiosyncratic Reaction
Nefazodone		Quinone iminium ion [263]	DILI [264]
Trazodone		Quinone iminium ion [263]	DILI [265]
Tienilic acid		Thiophene epoxide [266]	DILI [267]

Troglitazone

Sulfenic acid Isocyanate
Quinone methide
[268]

DILI [269]

Ketoconazole

?

DILI [270] Anaphylaxis
[271]

Perhexiline

?

DILI with steatosis
[272]

(continued overleaf)

TABLE 12.2 (Continued)

Drug	Structure	Reactive Metabolite	Idiosyncratic Reaction
Telithromycin		?	DILI [239]
Pyrazinamide		None known	DILI [273]

Drugs that are associated with predominately idiosyncratic liver injury along with the reactive metabolite(s) that have been proposed to be responsible for causing the liver injury. In some cases, the identity of the reactive metabolite is inferred from analogy with other drugs that have similar structures.

“?” indicates that no reactive metabolite has been described.

of mechanisms such as mitochondrial injury or epigenetic effects leading to an immune response, but this remains to be clearly demonstrated.

12.8 SUMMARY AND CONCLUSIONS

It is apparent that there is a large amount of circumstantial evidence to suggest that reactive metabolites are responsible for most IDRs. If the total daily dose is taken into account, there is a correlation between the amount of covalent binding of a drug and the risk that the drug will cause idiosyncratic liver toxicity. However, the correlation is far from perfect; there are drugs that form reactive metabolites and are not associated with a significant risk of IDRs, and there are drugs such as ximelagatran that cause serious IDRs but probably do not form a reactive metabolite. The formation of substantial amounts of reactive metabolite in a drug candidate that will be given at medium to high dose is a significant liability, and screening for reactive metabolites is likely to make drugs safer. However, there are significant false negatives and false positives in such screens no matter how carefully they are done. At present, it is not clear exactly how reactive metabolites cause IDRs, and some might even argue whether reactive metabolites cause IDRs. In most cases, the clinical characteristics of IDRs are most consistent with an immune mechanism. Progress in preventing IDRs will depend on finding answers to these questions. Valid animal models are important tools to answer these questions (see the chapter titled *Regulation of Drug Metabolizing Enzymes and Transporters in Infection, Inflammation, and Cancer*), but it is essential that any model or hypothesis has characteristics consistent with the IDRs observed in humans.

13.1 SUMMARY

The major depressive disorder schizophrenia and related disorders are among the most important causes of death and disability worldwide [1]. These disorders are highly prevalent, typically chronic or recurrent conditions with a substantial impact on public health. Therapy with antidepressant drugs is the standard of care for clinical depression; likewise, therapy with antipsychotics is required for schizophrenia.

The most important enzymes in psychotropic drug metabolism are the cytochrome P450 enzymes CYP2D6, CYP2C19, or CYP2C9. The functional impact of other drug-metabolizing enzymes including CYP1A2, CYP2A6, CYP2B6, CYP3A4, -5, and -7 or phase II enzymes in psychopharmacology is less, but some agents are cleared predominantly by these latter pathways.

The metabolism of psychotropic drugs may be assessed by *in vitro* studies and/or with *in vivo* pharmacokinetic studies. The clinical importance of drug metabolism is mainly determined by alteration of the individual activity of a relevant drug-metabolizing enzyme. This is frequently the case in drug–drug interactions, leading to enzyme inhibition or enzyme induction. Alternatively, individual patient

factors, such as pharmacogenetic polymorphisms, may contribute to variability in CYP isozyme activity.

Owing to the discrepancy between *in vitro* predictions of CYP-mediated metabolism and *in vivo* results on drug exposure, drug metabolism from *in vivo* studies will be preferentially presented in this chapter. A multitude of clinical metabolism data for psychotropic drugs exists because of the recognized importance of individual differences in drug exposure in clinical practice. As many psychotropic drugs are metabolized to equally active metabolites [2], more than one CYP isoform may be important in metabolism and exposure data of both metabolite and parent drug have to be taken into account. For many antidepressants or antipsychotic drugs, therapeutic drug monitoring is practiced regularly.

In the following pages, specific metabolism of antidepressant and antipsychotic drugs will be presented for the main CYP enzymes such as CYP2D6, CYP2C19, CYP2C9, and CYP1A2 (Table 13.1). Further, those metabolic pathways that are not typically used will be described for specific psychotropics. Special focus will be paid on the impact of genetically caused variations in enzyme activity and on drug–drug interactions, leading to changes in enzyme activity and drug metabolism (Table 13.2).

13.2 PSYCHOTROPIC DRUGS WITH METABOLISM BY CYP2D6

13.2.1 Antidepressants

13.2.1.1 Tricyclic Antidepressants. Depending on the amine side chain, tricyclic antidepressants (TCAs) can be classified into tertiary TCAs and secondary TCAs. Tertiary TCAs include amitriptyline, clomipramine, doxepin, trimipramine, and imipramine; and secondary TCAs include desipramine, nortriptyline, and protriptyline. Tertiary TCAs are first demethylated into secondary TCAs, which are further hydroxylated and conjugated. In the liver, CYP2D6 mediates the hydroxylation reactions [3–7] and CYP2C19 is responsible for demethylation of the parent drug. In certain cases, CYP3A4 may also act as a minor pathway for oxidative metabolism. Both hydroxylated and demethylated metabolites are pharmacologically active, and the demethylated metabolites are tricyclic drugs in themselves, for example, nortriptyline and desipramine (desmethyl metabolites of amitriptyline and imipramine, respectively). Nortriptyline and desipramine are mainly hydroxylated to less active or inactive metabolites [5,8]. For dose adaptation, the sum of pharmacologically active moieties (parent drug + demethylated metabolite) must be taken into account if data are available from therapeutic drug monitoring.

Stereoselective metabolism by CYP2D6 has been reported for trimipramine metabolism toward the less active L-trimipramine [6]. For doxepin, CYP2D6 polymorphisms affects only the clearance of the less active E-isomer [9]. For these two tricyclics, dose adjustments are usually based on the active drug compound (active enantiomers or isomer plus demethylated metabolite).

For several TCAs, no data on the specific enzymes involved in hydroxylation or demethylation reactions are available. However, structural similarity to other tricyclics such as imipramine implicates that CYP2D6 and CYP2C19 might be involved in metabolism of these tricyclics also.

An extremely high clearance was described for a few CYP2D6 ultrarapid metabolizers (UM) from studies with nortriptyline and desipramine, which are heavily

^c1.25- to 2-fold increase in the plasma AUC, 20–50% decrease in clearance or *in vitro* data only.

dependant on CYP2D6 for their metabolism. For nortriptyline, one UM carrying 13 active CYP2D6 genes was included, which was responsible for the very high mean of clearance in this group [10,11]. The frequency of CYP2D6 gene duplications varies between 10% and 50% in certain ethnic populations, including Eastern African, Arabian, and Pacific populations. In Europe, the UM phenotype is relatively rare at ~1–5% [12].

TCAs are known inhibitors of CYP1A2, CYP2C19, and CYP2D6, although the rank order varies between individual drugs. Nortriptyline and desipramine are usually considered as the least problematic of TCAs in terms of drug interactions since they are weak inhibitors of CYP2D6. The tertiary amine TCAs potently inhibit both CYP1A2 and 2C19 and are therefore more complicated to use with other drugs.

13.2.1.2 Selective Serotonin Reuptake Inhibitors. Some SSRIs (selective serotonin reuptake inhibitors) such as fluoxetine and paroxetine are potent inhibitors of CYP2D6 activity. These drugs also rely on CYP2D6 for their own oxidative metabolism. Therefore, multiple dosing causes decreased CYP2D6-mediated metabolism of the drugs themselves. Multiple dosing of these agents can also convert extensive metabolizers (EMs) of CYP2D6 into slow metabolizers [13–16]. Besides CYP2D6, paroxetine inhibits CYP2B6 quite strongly and causes a fourfold increase in plasma concentration of desipramine, a drug metabolized both via CYP2B6 and 2D6, when coadministered

[17]. Fluoxetine and its long-lived metabolite norfluoxetine are formed by CYP2D6 but also via other CYPs (2C9, 2C19, and 3A4). Owing to these alternative metabolic pathways, the plasma levels of fluoxetine are not usually affected by selective CYP inhibitors. Both fluoxetine and norfluoxetine are potent inhibitors of CYP2D6. However, fluoxetine and norfluoxetine inhibit also other CYPs besides CYP2D6. They have been shown to increase the concentrations of risperidone (a substrate of CYP2D and 3A4) when concomitantly used.

Sertraline and its active metabolite desmethylsertraline are partially metabolized by CYP2D6. Sertraline is considered to be a potent inhibitor of CYP2D6 when its daily doses exceed 150 mg. For sertraline and citalopram, no influence of CYP2D6 polymorphisms on pharmacokinetic parameters have been detected [13,18].

13.2.1.3 Other Antidepressants. Bupropion is primarily cleared by CYP2B6 and its metabolites are known to be potent inhibitors of CYP2D6. After treatment, phenotypically EMs of CYP2D6 appear pharmacokinetically similar to poor metabolizers (PMs) [19,20]. Thus, care should be exercised when bupropion is used concomitantly with drugs metabolized by CYP2D6, especially those with a narrow therapeutic index. In about 100 subjects, no major effects of CYP2B6 genotypes on bupropion pharmacokinetics were identified [21].

There are contradictory data regarding the effects of CYP2D6 poor metabolism status on the tetracyclic antidepressant maprotiline. Patients receiving monotherapy with 150 mg maprotiline showed no differences in steady state concentrations because of the debrisoquine metabolizer status [22]. A study with healthy volunteers receiving 100 mg maprotiline over seven days revealed differences similar to those detected in tricyclics [23].

For mianserin, CYP2D6 mediates enantioselective hydroxylation of the more active *S*-(+)-mianserin. For the racemic drug mirtazapine, *S*-(+)-mirtazapine clearance significantly depends on CYP2D6 activity but no such effect on *R*-(-)-mirtazapine clearance was found [24]. For moclobemide, reboxetine, and trazodone, CYP2D6 polymorphisms do not seem to have a major influence on metabolism in humans [25–30].

Venlafaxine is a chiral drug with both enantiomers transformed by CYP2D6 to the equipotent *O*-desmethylvenlafaxine [31–33]. A higher risk for cardiotoxic events and other adverse drug effects may exist in individuals lacking CYP2D6 activity [34]. Cases of severe arrhythmias have been reported in four patients treated with venlafaxine who all were CYP2D6 PMs [35]. On the other hand, efficacy was improved in individuals with high CYP2D6 activity in a metaanalysis of four studies [36].

13.2.2 CYP2D6 in the Metabolism of Antipsychotics

The influence of CYP2D6 polymorphisms on antipsychotic drug metabolism has been studied in humans for aripiprazole, clozapine, flupentixol, haloperidol, levomepromazine, olanzapine, perazine, perphenazine, pimozide, risperidone, thioridazine, and zuclopenthixol. The antipsychotic drug aripiprazole was studied for polymorphic CYP2D6 metabolism before marketing, and a 60% higher exposure of the total active moieties (parent drug and dehydroaripiprazole) was detected in PMs compared to EMs (aripiprazole product insert). In an observational study with schizophrenic patients receiving different doses, similar dependence on the genetically defined CYP2D6 phenotype was detected for flupentixol as well as for perazine [37].

For thioridazine, a recent study has revealed a 30% higher drug exposure in individuals who are CYP2D6 PMs [38]. This result corresponds to data from a study in healthy volunteers administering single doses of the drug [39], but it is in contrast to another study where smaller differences were found [40].

For haloperidol, CYP2D6 deficiency leads to a 60–70% lower clearance indicating that CYP2D6 is a principal pathway [9,41] but other studies have not reported significant CYP2D6 differences [42,43]. A significantly higher risk for extrapyramidal side effects in PMs was observed probably because of higher levels of the metabolite, the reduced form of haloperidol. Patients with UM genotype had the worst clinical outcome measured by the positive and negative symptoms scale which might be due to subtherapeutic haloperidol concentrations [9].

For perphenazine, thioridazine, and zuclopenthixol, steady state plasma drug concentrations decreased and resulting pharmacokinetic parameters were affected relative to those following single dose administration because of autoinhibition of CYP2D6. For olanzapine, although CYP1A2 is mainly involved in metabolism, in a comparative clinical study, steady state concentrations were correlated with CYP1A2 activity (influenced by smoking) but not by the CYP2D6 genotype [44]. Because zuclopenthixol is only metabolized partly via CYP2D6 and is also sulfoxidated and glucuronidated, CYP2D6 genotype seems to be less important [45].

Hydroxylation of risperidone at the 9-position is the most important metabolic pathway mediated mainly by CYP2D6 [46–49]. The total sum of plasma risperidone and 9-OH risperidone (paliperidone) is usually used as a determinant for risperidone pharmacological activity in therapeutic drug monitoring [50]. Since the sum of risperidone and 9-OH risperidone does not differ between CYP2D6 PMs and EMs, CYP2D6 polymorphism was hypothesized not to be important [50–53]. However, several studies have found an impact on 9-OH-risperidone plasma levels and CYP2D6 activity on risperidone effects. For example, in a recent report with children with pervasive developmental disorder treated with risperidone, serum prolactin level was positively correlated with the number of functional *CYP2D6* genes and serum 9-OH risperidone [54]. This and other studies have led to the proposal that the plasma profile for CYP2D6 PMs (characterized by higher risperidone than 9-OH risperidone concentrations) may be more “toxic” than for other phenotypes [55]. Accordingly, in one large study of adverse drug effects in 360 patients, PMs had more than a threefold increased risk (odds ratio, OR = 3.4) for significant risperidone adverse drug reaction (ADRs) and a sixfold increased risk of discontinuing risperidone (OR = 6.0) because of ADRs than EMs [56]. Thus, in the case of risperidone, clinicians should consider treating CYP2D6 PMs with an alternative antipsychotic drug or careful dosing under plasma concentration monitoring.

13.2.3 CYP2D6 in the Metabolism of Psychostimulants and Atomoxetine

Methylphenidate and amphetamines have a complex metabolism in which CYP2D6 has been postulated to play only a minimal role. In the case of atomoxetine, CYP2D6 is the principle enzyme responsible for the elimination of this drug, and atomoxetine itself is not known to inhibit any CYP. CYP2D6 metabolizer status affects the efficacy and tolerability of atomoxetine treatment, and coadministration of potent inhibitors of CYP2D6 results in altered pharmacokinetics similar to CYP2D6 PMs [57,58]. Thus, potent inhibitors of CYP2D6 (e.g., paroxetine and fluoxetine) should be coadministered with caution and careful monitoring of the treatment should be exercised.

13.3 IMPACT OF CYP2C19

There are currently over 50 available medications that are primarily metabolized by the CYP2C19 enzyme. The 2C19 substrate medications include widely used pharmaceuticals, such as most of the proton pump inhibitors (omeprazole, esomeprazole, lansoprazole, and pantoprazole), proguanil, and phenytoin, and some commonly prescribed psychotropic medications. A number of antidepressants are metabolized primarily or partially by CYP2C19, including amitriptyline, clomipramine, citalopram, and escitalopram [59]. In contrast, doxepin, imipramine, nortriptyline, sertraline, and moclobemide have substantial, but not exclusive, 2C19 substrate metabolic clearance.

Sertraline is metabolized by five cytochrome P450 enzymes (i.e., CYP2D6, CYP2C9, CYP2B6, CYP2C19, and CYP3A4). Consequently, the inhibition of any single CYP does not result in a major change in the pharmacokinetics of sertraline. However, CYP2C19 PMs have been shown to have higher serum levels of sertraline at a standard dose than do normal metabolizers. CYP2C19 phenotype may be of relevance for the clinical outcome of sertraline treatment, but thus are no unambiguous recommendations for dose adjustments available. The inhibition of CYP2B6 is reported to have a similar effect. The contribution of CYP2C9 and CYP3A4 to sertraline metabolism is minimal unless there is impaired CYP2C19 and CYP2B6 metabolic activity. The major metabolite of sertraline, desmethylsertraline, is a weak serotonin transporter reuptake inhibitor and does not have an important clinical pharmacological effect. Venlafaxine is minimally metabolized by the 2C19 isozyme.

The 2C19 isozyme plays a relatively circumscribed role in the metabolism of antipsychotic medication. It is substantially involved in the metabolism of clozapine and plays a minimal role in the metabolism of thioridazine. The 2C19 isozyme plays a primary role in the metabolism of diazepam. Diazepam is metabolized predominantly by 2C19 to nordiazepam, and then by 3A4 to oxazepam, which is then conjugated and excreted in urine. Diazepam is also metabolized to temazepam and then to oxazepam via CYP3A4. Although diazepam clearance has been shown to be decreased in CYP2C19 PMs or when inhibitors of CYP2C19 are concomitantly administered, the clinical impact is generally considered to be relatively small. The role of CYP2C19 in the metabolism of other benzodiazepines has not been well demonstrated.

13.4 IMPACT OF CYP2C9

13.4.1 Antidepressants

The cytochrome P450 2C9 gene (CYP2C9) codes for an enzyme that facilitates the oxidation of about 100 medications. These include drugs with a narrow therapeutic index, such as warfarin and phenytoin, as well as many of the nonsteroidal inflammatory drugs (NSAIDs). CYP2C9 is a polymorphically expressed enzyme, and some of the SNPs (single nucleotide polymorphisms) within this gene have been identified as contributors to the wide interindividual variation in the pharmacokinetics of certain drugs. The main variant alleles *2 and *3 are present in roughly 35% of Caucasian population, but they are much less prevalent in Asian and black populations.

Amitriptyline and fluoxetine are substantially metabolized by CYP2C9, and this CYP can play an important role in clearance if other metabolic pathways are

nonfunctional. Amitriptyline is demethylated by both CYP2C9 and CYP3A4 to produce nortriptyline, an active metabolite [60]. All existing data show only a minor contribution of CYP2C9 toward the interindividual pharmacokinetic variability of TCAs. Data on amitriptyline is based on *in vitro* studies only, and a small difference in kinetics between carriers of CYP2C9*1/*1 and *3/*3 was shown for trimipramine and doxepin [61]. Amitriptyline is known to be an inhibitor of CYPs, 1A2, 2C19, and 2D6.

Fluoxetine is metabolized primarily via N-demethylation by CYP2D6. Demethylation results in the production of norfluoxetine, which is also biologically active. Fluoxetine is metabolized secondarily by CYP2C9. Given the slow elimination of fluoxetine and the subsequent required secondary clearance of norfluoxetine, fluoxetine has the longest functional half-life of any SSRI antidepressants. In addition to its own metabolism by CYP2D6, fluoxetine is a suicide CYP2D6 inhibitor, which means that a strong and long-lasting CYP2D6 inhibition takes place after several doses of fluoxetine; and as a result, it may participate in drug interactions with other drugs that are metabolized by CYP2D6.

13.5 OTHER ENZYMES OR METABOLIC PATHWAYS

13.5.1 CYP1A2

There are over 40 currently available drugs that are primarily metabolized by the 1A2 isozyme. These include some commonly prescribed psychotropic medications such as antipsychotics clozapine and olanzapine and antidepressants fluvoxamine and mirtazapine. The 1A2 enzyme also plays an important secondary role in the metabolism of other psychotropic drugs when their primary pathways are not functional. This is the case with several TCAs. Besides psychotropics, CYP1A2 has a pivotal role in the metabolism of caffeine, theophylline, naproxen, tacrine, tizanidine, and some triptans such as frovatriptan and zolmitriptan. CYP1A2 is also responsible for metabolic activation of polycyclic aromatic hydrocarbons found in cigarette smoke.

The induction of CYP1A2 by smoking results in increased metabolic clearance and necessitates higher doses to achieve effective pharmacotherapy for drugs relying CYP1A2 [62]. During smoking cessation, the CYP1A2 activity will decrease and accumulation of parent drug will take place if dosing is not adjusted accordingly. Monitoring serum levels of drugs with narrow therapeutic indices (e.g., clozapine) during these transition periods is strongly recommended. The average plasma concentration of clozapine in smokers is about 50% of nonsmokers at the same dose. Seven to 12 cigarettes per day are necessary for maximal induction [63]. Schizophrenia patients smoke up to three times more than the general population and more than most psychiatric patients. When psychiatric hospital units were mandated to become nonsmoking in the United States, newly admitted patients who were smokers and who were taking clozapine had altered clearance of clozapine as CYP1A2 induction “wore off” during an extended stay. An opposite effect occurred on discharge. Many other psychotropics have been shown to have decreased concentrations in smokers: alprazolam, chlorpromazine, duloxetine, fluvoxamine, haloperidol, mirtazapine, olanzapine, and thioridazine.

13.5.1.1 Antidepressant Medications. The only antidepressant that is metabolized primarily by the CYP1A2 enzyme is the SSRI fluvoxamine. It has no active metabolites. It is a pan-CYP inhibitor, and it potently inhibits CYP1A2. Fluvoxamine has shown to raise serum clozapine concentrations drastically (about two- to threefold) whereas ciprofloxacin, a less potent inhibitor of CYP1A2 has a much weaker effect on clozapine metabolism. A recent study suggests that initiating treatment with 50 mg/day of fluvoxamine plus 100 mg/day of clozapine can be utilized with careful monitoring of levels [63].

Additionally, several other antidepressants including duloxetine, clomipramine, and imipramine [64–66] are substantially metabolized by the CYP1A2 enzyme. Mirtazapine and amitriptyline are minimally metabolized by CYP1A2, but the CYP1A2 genotype may be important for the metabolism of these antidepressants if their primary enzymes are inactive.

Duloxetine is an antidepressant that blocks the reuptake of serotonin and norepinephrine. It has also been reported to have an analgesic effect in patients with pain related to diabetic peripheral neuropathy. In addition to CYP1A2, CYP2D6 plays a role in the metabolism of duloxetine [67]. To a lesser extent, duloxetine blocks reuptake of dopamine at the receptors.

Clomipramine is a TCA that has been widely used for the treatment of obsessive-compulsive symptoms. In addition to CYP1A2, clomipramine is metabolized by CYP2C19, CYP3A4, and CYP2D6.

Mirtazapine is an antidepressant with a tetracyclic chemical structure that enhances both noradrenergic and serotonergic neurotransmission. In addition to CYP1A2, mirtazapine is metabolized by CYP2D6 and CYP3A4 [68]. Amitriptyline is a TCA that inhibits serotonin and noradrenaline reuptake almost equally. The major metabolic pathway for amitriptyline is primarily demethylation via CYP2C19 and results in the active metabolite, nortriptyline. Alternative minor pathways for the metabolism of amitriptyline are primary hydroxylation by CYP2D6 and demethylation by CYP1A2, CYP2C9, and CYP3A4 [69].

13.5.1.2 Antipsychotic Medications. The cytochrome P450 enzyme 1A2 catalyzes biotransformation of several antipsychotics [70]. Clozapine and olanzapine are predominantly metabolized by the CYP1A2 enzyme, and chlorpromazine is substantially metabolized by CYP1A2. Thioridazine and haloperidol are minimally metabolized by CYP1A2.

Clozapine was the first atypical antipsychotic. It has one major metabolite, which is also pharmacologically active. CYP1A2 is primarily responsible for clozapine metabolism. However, CYP2C19, CYP2D6, CYP2E1, CYP3A4, and CYP3A5 can provide alternative metabolic pathways. Olanzapine is an atypical antipsychotic that is primarily metabolized by CYP1A2 and secondarily by CYP2D6 and is further glucuronidated by uridine diphosphate glucuronosyltransferase (UGTs). Olanzapine does not inhibit or induce the CYP system. Induction of CYP1A2 by cigarette smoking is known to lead to reduced olanzapine concentrations and inhibition of CYP1A2 by fluvoxamine is known to increase olanzapine plasma levels. This latter drug interaction has been used as the basis for a strategy of increasing the concentration of olanzapine in smokers by administering nontherapeutic low dose fluvoxamine to smokers taking olanzapine [71]. Concomitant use of olanzapine with UGT-inhibitor probenecid and a wide spectrum inducer, carbamazepine, has shown

to reduce and increase its clearance, respectively [72,73]. Chlorpromazine was the first phenothiazine used to treat psychotic patients and has minimal effect on the serotonergic pathways. It is metabolized by both CYP1A2 and CYP2D6.

Haloperidol is a typical antipsychotic drug. It is primarily metabolized by CYP3A4 and CYP2D6. However, CYP1A2 also contributes to haloperidol's metabolism, as has been demonstrated by evaluating patients who have received a CYP1A2 inhibitor and subsequently experienced increased serum levels of haloperidol [74].

Thioridazine is a phenothiazine that is a racemic compound with two enantiomers. Both enantiomers are metabolized by CYP2D6, but the CYP1A2 metabolism becomes important for patients who are taking thioridazine and who are poor 2D6 metabolizers.

Some data exist on higher drug concentrations and higher risks for tardive dyskinesia in schizophrenic patients who are smokers and carriers of CYP1A2 genotypes with reduced inducibility (C/A polymorphism at position 734 in intron 1 and G/A polymorphism at position -2964 in the 5'-flanking region of CYP1A2) but with contradictory results [75-77].

13.5.1.3 Other Drugs. Melatonin, melatonin receptor agonist, ramelteon (used as a treatment for insomnia), and melatonin analog, agomelatine (used as an antidepressant) rely mainly on CYP1A2 for their metabolism. Coadministration with fluvoxamine has shown to lead to significantly increased plasma levels of these drugs [78,79].

13.5.2 Drugs Metabolized by CYP2B6, CYP3A4, and Other Pathways

13.5.2.1 Antidepressants. CYP2B6 is the main metabolic enzyme in bupropion metabolism, and polymorphisms in CYP2B6 may be relevant for bupropion, but the differences due to genotype are small [21]. Certain non-nucleoside reverse transcriptase inhibitors (efavirenz, nelfinavir) and viral protease inhibitors (ritonavir) have been shown to inhibit bupropion metabolism, but convincing documentation concerning the clinical relevance of this interaction is currently lacking.

13.5.2.2 Antipsychotics. For iprindole, isocarboxazid, setipiline, and viloxazine, elimination occurs mainly via conjugation reactions (glucuronidation, acetylation, and sulfation). The specific phase II enzymes catalyzing these reactions are not known. Renal excretion is the principle route for phenelzine, tranlylcypromine, and milnacipran. Tianeptine as well as reboxetine seem to be mainly metabolized by CYP3A4 [80]. Buspirone is metabolized by CYP3A4 to the active metabolite, 1-(2-pyrimidinyl)-piperazine (1-PP) [81]. Inhibitors of CYP3A4, for example, diltiazem, erythromycin, grapefruit juice, itraconazole, and nefazodone have shown to greatly increase plasma buspirone concentrations and side effects. Coadministration of buspirone and CYP3A4 inhibitors should be preferably avoided, or the dose of buspirone should be greatly reduced during the concomitant treatment. Buspirone is also vulnerable to potent CYP3A4 inducers such as rifampin and others.

Elimination pathways other than those involving cytochrome P450 enzymes are important for the following antipsychotics: sulpiride, amisulpride, paliperidone (renal excretion), raclopride (glucuronidation, sulfation), and zotepine (flavin-monooxygenases involved). CYP3A4 is the main enzyme involved in metabolism of bromperidole, iloperidone, perospirone, and quetiapine [82,83]. Ziprasidone is metabolized primarily by aldehyde oxidase with a minor contribution of CYP3A4. Wakefulness-promoting drugs armodafinil and modafinil are metabolized mainly

by CYP3A4 and glucuronide conjugation. For chlorpromazine, remoxipride, and sertindole, only *in vitro* data exist on involvement of CYP2D6 [83]. Remoxipride and sertindole were withdrawn from the market because of adverse drug reactions (aplastic anemia and arrhythmia), but sertindole was recently been reintroduced to the European market. Melperone is described as potent inhibitor of CYP2D6, but studies on impact of variability in CYP2D6 activity (through genetic polymorphisms) on melperone metabolism do not yet exist [84].

13.6 CONCLUSIONS

Twenty years ago, a clinician would not have been able to anticipate possible drug interactions involving psychotropics. There has been an avalanche of data about these drugs since then. With the help of the information about the metabolism of psychotropics in this chapter, clinicians are now in a much better position to “predict” possible drug interactions. Further, the information about what drugs demonstrate P450 cytochromal genetic variations provide guidance to clinicians in deciding who would be candidates for P450 CYP genetic testing.

14.1 SUMMARY

Antiepileptic drugs (AEDs) are the mainstay of epilepsy treatment, and there are now 22 AEDs licensed for clinical use and more are under development. Because of the long-term nature of epilepsy treatment and the fact that invariably patients will be prescribed nonepilepsy drugs consequent to comorbidities, the potential for pharmacokinetic interactions in general and metabolic interactions in particular is substantial. The older first-generation AEDs (carbamazepine, phenobarbital, phenytoin, and valproic acid) undergo metabolism via common cytochrome P450 (CYP) isoenzymes that are highly inducible and readily inhibited, and these AEDs are associated with many hundreds of metabolic interactions. Additionally, carbamazepine, phenobarbital, phenytoin, and valproic acid have a substantial ability to induce and/or inhibit hepatic metabolism. Although some of the new second- and third-generation AEDs are susceptible to inhibition and induction of their own metabolism (e.g., eslicarbazepine acetate,

felbamate, lamotrigine, oxcarbazepine, tiagabine, topiramate, and zonisamide), overall, they are less interacting because they are not substantial inducers or inhibitors of hepatic metabolism. Furthermore, AEDs such as gabapentin, levetiracetam, pregabalin, and vigabatrin, which are primarily renally excreted, are not amenable to interference. Similarly, AEDs such as lacosamide and rufinamide that are not metabolized by CYP isoenzymes or uridine glucuronyl transferases are also not amenable to interference. There are various new putative AEDs under development, and it would appear that these AEDs also have a low propensity for metabolic interactions. Clinically, there is always a choice, and all things being equal, particularly if neither the physician nor the patient wishes to worry about metabolic interactions and their consequence (induction can result in seizure breakthrough, while inhibition can result in concentration-related toxicity), the AEDs of choice are gabapentin, lacosamide, levetiracetam, pregabalin, and vigabatrin. However, in many clinical settings polytherapy with known interacting drugs is unavoidable, and it is best practice to manage such interactions by undertaking graded therapeutic dose adjustments that are guided by blood level measurements of the affected drug.

14.2 INTRODUCTION

Approximately 1% of the world population is affected by epilepsy, a chronic disorder that usually persists for many years and often for a lifetime [1]. The mainstay of treatment is the use of AED monotherapy, and this approach can render ~65% of newly diagnosed patients seizure-free [2]. For the remaining 35% of patients, prescribing polytherapy (two or more drugs) AED regimens so as to achieve optimal seizure control is a common practice. However, for the majority of these patients, little additional benefit is achieved from the use of polytherapy AEDs, as intolerable adverse effects commonly occur as a consequence of pharmacokinetic and/or pharmacodynamic interactions.

As a class of drugs, the AEDs are associated with more interactions than any other therapeutic drug class, and this is because (i) most AEDs have a narrow therapeutic index so that even small changes in their plasma concentration can result in seizure exacerbation or increased adverse effects; (ii) the most widely used AEDs (carbamazepine, phenobarbital, phenytoin, and valproic acid) have a substantial ability to induce and/or inhibit hepatic metabolism; (iii) additionally, these AEDs, along with some of the newer AEDs (e.g., eslicarbazepine acetate, lamotrigine, tiagabine, topiramate, oxcarbazepine, felbamate, and zonisamide), are susceptible to inhibition and induction of their own metabolism [3–6]. Additional confounding factors include the following: (i) those patients who respond to monotherapy may also experience the consequences of AED interactions as AEDs are added and withdrawn during the optimization of their monotherapy drug regimen; (ii) polytherapy AED regimens are often required to treat patients with multiple seizure types; (iii) since epilepsy is a chronic condition, many patients will inevitably develop comorbid diseases or other debilitating conditions and disorders, which will require the coadministration of non-AED drugs, and in this setting, the potential for drug interactions is considerable; (iv) the increasing use of over-the-counter medications and dietary supplements, many of which have unknown constituents and are of variable quality, that can interact with AEDs; and

(v) AEDs are increasingly used to treat other nonepilepsy conditions such as mood disorders, migraine, and pain, thereby further increasing the possibility of combined use with other drugs [7,8]. Finally, with regard to new AEDs, although with time they may be licensed for monotherapeutic use, these drugs, at least when first licensed, can only be prescribed for adjunctive therapy; therefore, polytherapy will be the only option for new AEDs, and their propensity to interact is a major consideration during their clinical evaluation.

This chapter reviews the mechanisms of interaction that can occur with AEDs, with particular emphasis on metabolic interactions. Subsequently, the AEDs are reviewed in alphabetical order in terms of their metabolism, their effects on other drugs, and the effect of other drugs on their metabolism. Finally, AEDs under development are reviewed.

14.3 MECHANISMS OF DRUG INTERACTION

Interactions can be divided into two groups: pharmacokinetic and pharmacodynamic interactions.

1. *Pharmacokinetic Interactions* These involve a change in the absorption, usually gastrointestinal; distribution, usually binding to serum albumin; metabolism, usually by isoenzymes of CYP and uridine glucuronyl transferases (UGTs); or elimination, usually renal excretion, of the affected drug and consequently altering concentrations (levels) at the site of drug action. Pharmacokinetic interactions are particularly prevalent and are associated with a change in plasma level of either the drug or its metabolite(s) or both.
2. *Pharmacodynamic Interactions* Pharmacodynamic interactions occur at the cellular level where drugs act and can occur between drugs that have either similar or opposing pharmacological mechanisms of action. Because these interactions are not associated with any change in plasma drug level, they are less well recognized and documented. Nevertheless, they are of major clinical significance.

14.4 METABOLIC INTERACTIONS AND HEPATIC ISOENZYMES

By far, the most clinically significant pharmacokinetic interactions with AEDs are those related to changes in hepatic metabolism and involve induction or inhibition of drug metabolism. With the exception of gabapentin, levetiracetam, pregabalin, and vigabatrin, all AEDs undergo hepatic metabolism and consequently are susceptible to inhibitory and/or induction interactions. Although metabolic drug interactions may involve changes in any one of the numerous enzymes involved in drug metabolism, by far, the most important are those associated with the CYP and UGT systems. The CYP system is particularly important because it is responsible for the oxidative metabolism of many drugs and exogenous compounds, as well as many endogenous compounds such as prostaglandins, fatty acids, and steroids.

14.4.1 CYP Enzymes

The CYP enzyme system consists of a superfamily of isoenzymes that are located in the smooth endoplasmic reticulum, primarily in the liver but also in many other tissues (e.g., intestine, kidney, brain, and placenta). Although in man ~60 different CYP isoenzymes have been identified, 7 isoenzymes (CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4) are known to be responsible for the metabolism of 95% of all drugs [9,10]. The most abundant isoenzyme is CYP3A4, which accounts for ~30% of all CYPs, has the broadest substrate specificity and is involved in more than 50% of all drug metabolism [11]. Three isoenzymes (CYP2C9, CYP2C19, and CYP3A4) are of particular importance in relation to AED interactions. Valproic acid, felbamate, and stiripentol are potent inhibitors of CYPs, while eslicarbazepine acetate, topiramate, oxcarbazepine, and rufinamide are moderate inhibitors. In contrast, carbamazepine, phenytoin, phenobarbital, and primidone act as broad-spectrum inducers of CYPs, while lamotrigine, oxcarbazepine, rufinamide, and topiramate act more specifically on CYP isoenzymes. Noteworthy is the fact that some AEDs (oxcarbazepine, rufinamide, topiramate) act as both inhibitors and inducers of CYPs.

14.4.2 Epoxide Hydrolases

Microsomal epoxide hydrolase is involved in xenobiotic metabolism and plays an important role in the metabolism of carbamazepine, phenobarbital, and phenytoin. Carbamazepine-10,11-epoxide (carbamazepine epoxide), the pharmacologically active metabolite of carbamazepine, has been implicated in various important interactions. Valproic acid and felbamate are potent inhibitors of epoxide hydrolase, while phenytoin, phenobarbital, and primidone act as inducers.

14.4.3 Uridine Glucuronyl Transferases

Various families of UGTs have been identified, of which UGT1 and UGT2 appear to be the most important in drug metabolism [12]. The UGT1A3 and UGT2B7 isoforms are involved in the O-glucuronidation of valproic acid, and UGT1A4 has been found to be the major isoform responsible for the metabolism (N-glucuronidation) of lamotrigine. Valproic acid inhibits several UGTs, while carbamazepine, phenobarbital, phenytoin, and primidone are inducers.

14.5 ENZYME INDUCTION

Enzyme induction is the consequence of an increase in enzyme protein resulting from an increase in gene transcription that is mediated by intracellular receptors. The resultant elevated enzyme activity results in an increase in the rate of metabolism of the affected drug, leading to a decrease in plasma level and possibly a reduction in the therapeutic response. If the affected drug has a pharmacologically active metabolite, induction can result in increased metabolite levels and possibly an increase in drug toxicity. The time course of induction is usually gradual and dose dependent and is dependent on the rate of enzyme synthesis and/or degradation as well as the time to reach plasma steady-state levels of the inducing drug. The latter is usually the rate-limiting step and

only occurs at a time which is approximately five elimination half-lives of the inducing drug. Similarly, the rate-limiting step in deinduction is the elimination of the inducing drug. When the inducer is removed, plasma levels of the affected drug will increase and serious adverse effects can occur if the dose of the affected drug is not reduced.

Enzyme induction represents a common problem in the management of epilepsy. Phenobarbital, carbamazepine, and phenytoin are potent inducers of CYPs, although phenytoin and carbamazepine appear to be less potent inducers at doses used clinically.

14.6 ENZYME INHIBITION

Enzyme inhibition is the consequence of competition by drugs to bind to the same enzymic site, resulting in a reduction of enzyme activity and a decrease in the rate of metabolism of the affected drug. Inevitably, plasma levels are elevated, and this can result in clinical toxicity. Inhibition is usually competitive in nature and therefore dose dependent and tends to begin as soon as sufficient levels of the drug inhibitor are achieved, which usually occurs within 24 hours of inhibitor addition. The time to maximal inhibition will depend on the elimination half-life of the affected drug and the inhibiting agent.

Among the AEDs, valproic acid, topiramate, and felbamate have been associated with inhibitory interactions. Furthermore, while topiramate and felbamate are primarily selective inhibitors of CYP2C19, valproic acid is considered to be a broad-spectrum inhibitor of hepatic metabolizing enzymes, as it inhibits CYP2C9, UGTs, and microsomal epoxide hydrolase.

An AED may be the affected drug or the cause of an interaction. In fact, with some drug combinations, the hepatic metabolism of both the AED and the other drug is altered. For example, during comedication with erythromycin and carbamazepine, carbamazepine plasma levels are elevated two- to fourfold due to inhibition of carbamazepine metabolism. Conversely, the effectiveness of standard dosages of erythromycin is reduced because carbamazepine enhances the metabolism of erythromycin. Other bidirectional interactions include those between topiramate and phenytoin and between valproic acid and lamotrigine.

14.7 ANTIEPILEPTIC DRUGS LICENSED FOR CLINICAL USE

14.7.1 Carbamazepine

Carbamazepine is metabolized in the liver, primarily by CYP3A4 with some contribution by CYP2C8, to carbamazepine epoxide, which is pharmacologically active. Carbamazepine epoxide is in turn metabolized, via epoxide hydrolase, to an inactive *trans*-carbamazepine diol. Overall, carbamazepine has a substantial propensity for metabolic interactions and acts as an inducer of metabolism.

14.7.1.1 Effect of Carbamazepine on Other Drugs. Carbamazepine induces both the metabolism of drugs metabolized by various CYPs and UGTs and its own metabolism. Autoinduction usually occurs within one week of carbamazepine initiation and completes within three to four weeks [13].

Carbamazepine induces the metabolism of many AEDs, the clinical significance of which varies from modest, where the partial loss of efficacy resulting from the decreased plasma level of the affected drug is compensated for by the antiepileptic effect of the added carbamazepine, to substantial, where the decrease in AED level is so pronounced that seizure control will be lost unless the dosage of the affected drug is increased. Modest effects occur with oxcarbazepine, phenytoin, primidone, and rufinamide, while substantial effects occur with clobazam, clonazepam, ethosuximide, lamotrigine, stiripentol, topiramate, tiagabine, valproic acid, and zonisamide (Table 14.1). Carbamazepine can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2).

Carbamazepine also induces the metabolism of many non-AED drugs (Table 14.3), the magnitude of which is particularly substantial for those drugs that undergo extensive first-pass metabolism, so that plasma levels may be decreased significantly. Such drugs include antifungals (e.g., itraconazole, ketoconazole), antihelmintics (e.g., albendazole, praziquantel), antituberculous agents (e.g., indinavir, nelfinavir), and dihydropyridine calcium antagonists (e.g., nimodipine, nifedipine) [14–17]. Additionally, carbamazepine can induce the metabolism of various antineoplastic agents (e.g., 9-aminocamptothecin, teniposide, methotrexate), so that their plasma levels decrease significantly [18–20].

14.7.1.2 Effect of Other Drugs on Carbamazepine. When considering the effect of other drugs on carbamazepine, one also needs to consider the effects on the active metabolite which is rarely measured clinically. For example, valproic acid inhibits epoxide hydrolase, the enzyme that is responsible for the metabolism of carbamazepine epoxide and has no effect on CYP3A4. Thus, carbamazepine-related toxicity can occur in the absence of any change in carbamazepine plasma levels [21,22]. Similarly, while the antipsychotic quetiapine does not affect plasma carbamazepine levels, plasma carbamazepine epoxide levels increase three- to fourfold, causing carbamazepine-related toxicity. In contrast, fluoxetine inhibits the metabolism of carbamazepine so that both carbamazepine and carbamazepine epoxide plasma levels increase and patients show significant signs of toxicity with what might appear to be only small increases in carbamazepine plasma levels [23,24]. Interestingly, felbamate increases carbamazepine epoxide plasma levels but decreases carbamazepine plasma levels. While phenobarbital and phenytoin can induce the metabolism of carbamazepine, stiripentol inhibits its metabolism increasing plasma levels several fold [25].

There are numerous non-AED drugs that are potent inhibitors of CYP3A4, and their coadministration with carbamazepine can result in carbamazepine-related toxicity. Such drugs include antidepressants (e.g., fluoxetine, fluvoxamine, nefazodone, trazodone, viloxazine), antimicrobials (clarithromycin, erythromycin, fluconazole, isoniazid, itraconazole, josamycin, ketoconazole, metronidazole, ritonavir, troleandomycin), and the calcium channel blockers diltiazem and verapamil [4,6]. Because up to threefold increases in plasma carbamazepine levels can occur, this can result in serious clinical toxicity.

14.7.2 Clobazam

Clobazam is metabolized in the liver, primarily by desmethylation, to *N*-desmethyloclobazam, which is pharmacologically active. Clobazam also undergoes

Vigabatrin	—	Yes
Zonisamide	—	Yes

^aLamotrigine has no effect on the estrogen component of a contraceptive pill and in most patients will not compromise contraception. However, lamotrigine can enhance the metabolism of the progesterone component so that progesterone blood levels decrease by ~10%. This effect may be clinically significant in some patients prescribed the progesterone-only contraceptive pill.

^bThe effect of stiripentol on hormonal contraception is unknown. However, theoretically, stiripentol may increase plasma levels of hormonal contraceptives and thus necessitate lower doses to be prescribed. Because stiripentol has a very limited indication, it is not expected to be prescribed during pregnancy or to women of childbearing potential.

metabolism by hydroxylation to form other metabolites, namely, 4-hydroxyclobazam and 4-hydroxydesmethyloclobazam. The *N*-desmethyloclobazam metabolite contributes significantly to the efficacy of clobazam. Overall, clobazam has a low propensity for metabolic interactions.

14.7.2.1 Effect of Clobazam on Other Drugs. Clobazam can inhibit the metabolism of phenytoin, primidone, and valproic acid so that their plasma levels increase (Table 14.1). Clobazam does not interfere with the metabolism of other non-AED drugs. The metabolism of oral contraceptives is unaffected by clobazam, and therefore, clobazam does not compromise contraceptive control (Table 14.2).

14.7.2.2 Effect of Other Drugs on Clobazam. The prominent interaction feature of clobazam is its vulnerability to hepatic induction so that carbamazepine, felbamate,

TABLE 14.3 Non-AED Drugs Whose Plasma Levels are Decreased Consequent to Induction by Enzyme-Inducing AEDs (Carbamazepine, Phenobarbital, Phenytoin, and Primidone)

Analgesics	<i>Carbamazepine:</i> fentanyl, meperidine, methadone, and paracetamol <i>Phenytoin:</i> fentanyl, meperidine, methadone, paracetamol, and pethidine <i>Phenobarbital:</i> fentanyl, meperidine, methadone, and paracetamol <i>Primidone:</i> fentanyl, meperidine, methadone, and paracetamol
Antimicrobials	<i>Carbamazepine:</i> albendazole, delavardine, doxycycline, efavirenz, erythromycin, indinavir, isoniazid, itraconazole, ketoconazole, mebendazole, nelfinavir, nevirapine, praziquantel, ritonavir, saquinavir, zidovudine <i>Phenobarbital:</i> albendazole, chloramphenicol, delavardine, doxycycline, efavirenz, indinavir, itraconazole, ketoconazole, metronidazole, nelfinavir, nevirapine, praziquantel, ritonavir, saquinavir, zidovudine <i>Phenytoin:</i> albendazole, delavardine, doxycycline, efavirenz, erythromycin, indinavir, itraconazole, ketoconazole, mebendazole, nelfinavir, nevirapine, praziquantel, ritonavir, saquinavir, voriconazole, zidovudine <i>Primidone:</i> delavardine, efavirenz, indinavir, nelfinavir, nevirapine, ritonavir, saquinavir, zidovudine
Antineoplastic drugs	<i>Carbamazepine:</i> 9-aminocamptothecin, docetaxel, methotrexate, paclitaxel, procarbazine, teniposide, vincristine <i>Phenobarbital:</i> 9-aminocamptothecin, docetaxel, etoposide, ifosfamide, methotrexate, paclitaxel, procarbazine, teniposide, vincristine <i>Phenytoin:</i> 9-aminocamptothecin, busulfan, cyclophosphamide, docetaxel, etoposide, ifosfamide, irinotecan, methotrexate, paclitaxel, procarbazine, teniposide, topotecan, vincristine <i>Primidone:</i> although the effect of primidone on the metabolism of antineoplastic drugs has not been determined, similar interactions would be expected as those described for phenobarbital
Cardiovascular drugs	<i>Carbamazepine:</i> amiodarone, dicoumarol, felodipine, nimodipine, nivaldipine, phenprocoumon, warfarin <i>Phenobarbital:</i> alprenalol, dicoumarol, felodipine, nifedipine, nimodipine, propranolol, quinidine, verapamil, warfarin <i>Phenytoin:</i> amiodarone, dicoumarol, digoxin, disopyramide, felodipine, losartan,^a mexiletine, nimodipine, nisoldipine, quinidine, verapamil, warfarin^b <i>Primidone:</i> dicoumarol
Immunosuppressants	<i>Carbamazepine:</i> cyclosporine A <i>Phenobarbital:</i> cyclosporine A <i>Phenytoin:</i> cyclosporine A, sirolimus, tacrolimus <i>Primidone:</i> cyclosporine A

(continued overleaf)

TABLE 14.3 (Continued)

Psychotropic drugs	<i>Carbamazepine</i>: alprozolam, amitriptyline, citalopram, clobazam, clomipramine, clonazepam, clozapine, desipramine, desmethylclomipramine, diazepam, doxepin, fluphenazine, haloperidol, imipramine, mianserin, midazolam, mirtazapine, nefazodone, nortriptyline, olanzapine, paroxetine, protriptyline, quetiapine, risperidone, sertraline, thioridazine, ziprasidone <i>Phenobarbital</i>: alprozolam, amitriptyline, citalopram, clobazam, clomipramine, clonazepam, chlorpromazine, clozapine, desipramine, desmethylclomipramine, diazepam, fluphenazine, haloperidol, imipramine, mianserin, midazolam, nefazodone, nortriptyline, olanzapine, paroxetine, protriptyline, quetiapine, risperidone, ziprasidone <i>Phenytoin</i>: alprozolam, amitriptyline, citalopram, clobazam, clomipramine, clonazepam, clozapine, desipramine, desmethylclomipramine, diazepam, fluphenazine, haloperidol, imipramine, mianserin, midazolam, mirtazapine, nefazodone, nortriptyline, olanzapine, paroxetine, protriptyline, quetiapine, risperidone, thioridazine, ziprasidone <i>Primidone</i>: alprozolam, amitriptyline, citalopram, clobazam, clomipramine, clonazepam, desipramine, desmethylclomipramine, diazepam, fluphenazine, haloperidol, imipramine, midazolam, nefazodone, nortriptyline, olanzapine, paroxetine, protriptyline, quetiapine, risperidone, ziprasidone
Steroids	<i>Carbamazepine</i>: cortisol, dexamethasone, hydrocortisone, methylprednisolone, prednisolone, steroid oral contraceptives <i>Phenobarbital</i>: cortisol, dexamethasone, hydrocortisone, methylprednisolone, prednisolone, steroid oral contraceptives <i>Phenytoin</i>: cortisol, dexamethasone, hydrocortisone, methylprednisolone, prednisolone, steroid oral contraceptives <i>Primidone</i>: steroid oral contraceptives
Miscellaneous	<i>Carbamazepine</i>: bupropion, cisatracurium, doxacurium, lidocaine, omeprazole, pancuronium, rapacurium, rocuronium, theophylline, vecuronium <i>Phenobarbital</i>: bupropion, lidocaine, omeprazole, theophylline <i>Phenytoin</i>: bupropion, cisatracurium, doxacurium, lidocaine, omeprazole, pancuronium, rapacurium, rocuronium, theophylline, vecuronium <i>Primidone</i>: bupropion, lidocaine, rocuronium

^aOnly pharmacologically active carboxylic acid metabolite (E3174) is affected.

^bA biphasic interaction occurs, where initially phenytoin acts as an inhibitor and subsequently induction prevails.

phenobarbital, phenytoin, and primidone enhance its metabolism, resulting in a decrease in clobazam plasma levels but with a concurrent increase in levels of the pharmacologically active metabolite *N*-desmethylclobazam. It is not known whether the increase in metabolite levels compensates for the decrease in clobazam levels, but typically, higher doses of clobazam are warranted during comedication with these AEDs. Noteworthy is the interaction with stiripentol, which serves as a potent inhibitor, so that both clobazam

and *N*-desmethyloclobazam plasma levels increase by manyfold [26]. Cimetidine can increase clobazam levels by ~17% without affecting plasma *N*-desmethyloclobazam levels.

14.7.3 Clonazepam

Clonazepam is metabolized in the liver, primarily by CYP3A4, to 7-amino-clonazepam that is in turn metabolized by acetylation, via *N*-acetyltransferase, to form 7-acetamido-clonazepam. Clonazepam is also hydroxylated (isoenzymes not identified) to form 3-hydroxyclonazepam. Although the 7-amino-clonazepam metabolite retains some pharmacological activity, none of the other metabolites of clonazepam are pharmacologically active. Overall, clonazepam has a minimal propensity for metabolic interactions.

14.7.3.1 Effect of Clonazepam on Other Drugs. To date, there have been no reports of clonazepam affecting the clearance of other AEDs or non-AED drugs. The metabolism of oral contraceptives is unaffected by clonazepam, and therefore, it does not compromise contraceptive control (Table 14.2).

14.7.3.2 Effect of Other Drugs on Clonazepam. The AEDs carbamazepine, lamotrigine, phenobarbital, and phenytoin can increase the clearance of clonazepam and decrease clonazepam plasma levels, while amiodarone and ritonavir can decrease its clearance and increase clonazepam plasma levels.

14.7.4 Eslicarbazepine Acetate

Eslicarbazepine acetate is rapidly metabolized (hydrolysis) in the liver to its pharmacologically active metabolite, eslicarbazepine (also known as *S*-licarbazepine), by esterases (91%). Other minor metabolites, which are pharmacologically active, include *R*-licarbazepine (~5%) and oxcarbazepine (~1%). Eslicarbazepine (33%) is subsequently metabolized by conjugation with glucuronic acid. Although the metabolites of eslicarbazepine acetate are pharmacologically active, they contribute to <5% of activity. Overall, eslicarbazepine acetate has a minimal propensity for metabolic interactions.

14.7.4.1 Effect of Eslicarbazepine Acetate on Other Drugs. Eslicarbazepine can increase plasma levels of phenytoin presumably via inhibition of either CYP2C9 or CYP2C19, while lamotrigine and topiramate plasma levels are decreased. Additionally, eslicarbazepine can decrease plasma levels of warfarin [27]. Eslicarbazepine can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2).

14.7.4.2 Effect of Other Drugs on Eslicarbazepine Acetate. Carbamazepine and phenytoin can increase the clearance of eslicarbazepine and decrease eslicarbazepine plasma levels. To date, there have been no reports of other drugs affecting the clearance and plasma levels of eslicarbazepine [27].

14.7.5 Ethosuximide

Ethosuximide is metabolized in the liver by hydroxylation to form isomers of 2-(1-hydroxyethyl)-2-methylsuccinimide, of which at least 40% are glucuronide conjugates. Metabolism is primarily mediated by CYP3A and to a lesser extent by CYP2E and CYP2B/C. Overall, ethosuximide has a low propensity for metabolic interactions.

14.7.5.1 Effect of Ethosuximide on Other Drugs. At therapeutic doses, ethosuximide is not associated with induction or inhibition of hepatic enzymes, and to date, there has been no reports of ethosuximide affecting the clearance of other drugs. The metabolism of oral contraceptives is unaffected by ethosuximide, and therefore, it does not compromise contraceptive control (Table 14.2).

14.7.5.2 Effect of Other Drugs on Ethosuximide. Carbamazepine, phenobarbital, phenytoin, and primidone can induce the metabolism of ethosuximide and decrease its plasma levels, while valproic acid can inhibit ethosuximide metabolism and increase its plasma levels (Table 14.1). Furthermore, while rifampicin can induce the metabolism of ethosuximide and decrease its plasma levels, isoniazid and ritonavir can inhibit its metabolism and increase plasma levels.

14.7.6 Felbamate

Only 50% of the administered dose is metabolized in the liver, by CYP3A4 and CYP2E1, to form two hydroxylated metabolites (*para*-hydroxyfelbamate and 2-hydroxyfelbamate; 10–15%) and a variety of other unidentified polar metabolites, some of them being glucuronides or sulfate esters. Overall, felbamate has a moderate propensity for metabolic interactions and acts as an inhibitor of metabolism.

14.7.6.1 Effect of Felbamate on Other Drugs. Felbamate is both an inhibitor of drugs metabolized by CYP2C19 and β oxidation and an inducer of drugs metabolized by CYP3A4 [28]. Thus, felbamate inhibits the metabolism of phenobarbital, phenytoin, and valproic acid and increases their plasma levels but decreases the level of carbamazepine (18–31%) while increasing carbamazepine epoxide levels (33–57%) [29]. Felbamate can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2).

14.7.6.2 Effect of Other Drugs on Felbamate. Carbamazepine, phenytoin, and phenobarbital can induce the metabolism of felbamate, so that its clearance is increased by 40–82% [28]. To date, there have been no reports of other non-AED drugs affecting the metabolism of felbamate.

14.7.7 Gabapentin

Gabapentin is not metabolized, is excreted unchanged in urine, and, as such, is neither a hepatic enzyme inducer nor an inhibitor. To date, gabapentin has not been associated with any clinically significant metabolic interactions.

14.7.8 Lacosamide

Lacosamide undergoes moderate metabolism in the liver, by demethylation to *O*-desmethyl lacosamide (30%). Other unidentified metabolites constitute a further 30% of the metabolism. CYP2C19 is considered to be primarily responsible for the formation of *O*-desmethyl lacosamide, and none of the metabolites are pharmacologically active.

14.7.8.1 Effect of Lacosamide on Other Drugs. Although lacosamide undergoes moderate hepatic metabolism, it is essentially non-CYP-dependent and, as such, is not amenable to interference. To date, lacosamide has not been associated with any clinically significant metabolic interactions affecting other drugs [30].

14.7.8.2 Effect of Other Drugs on Lacosamide. To date, the metabolism of lacosamide has not been affected by other drugs, and thus is not associated with any clinically significant metabolic interactions [30].

14.7.9 Lamotrigine

Lamotrigine undergoes extensive metabolism in the liver, by conjugation with glucuronic acid, to various metabolites including, 2-*N*-glucuronide (76% of dose) and 5-*N*-glucuronide (10% of dose), a 2-*N*-methyl metabolite (0.14% of dose), and other unidentified minor metabolites (4% of dose). The isoform that is responsible for the *N*-glucuronidation of lamotrigine is UGT1A4. The metabolites of lamotrigine are not pharmacologically active. Overall, lamotrigine has a moderate propensity for metabolic interactions.

14.7.9.1 Effect of Lamotrigine on Other Drugs. Lamotrigine is a weak inhibitor of UGT, and it induces its own metabolism and causes a small decrease in plasma levels of clonazepam and valproic acid [31]. To date, there have been no reports of lamotrigine affecting the clearance and plasma levels of other non-AED drugs. The metabolism of oral contraceptives is unaffected by lamotrigine, and therefore, it does not compromise contraceptive control (Table 14.2).

14.7.9.2 Effect of Other Drugs on Lamotrigine. Carbamazepine, methsuximide, oxcarbazepine, phenobarbital, phenytoin, and primidone can increase the clearance of lamotrigine and decrease lamotrigine plasma levels. In contrast, valproic acid can decrease the clearance of lamotrigine and increase lamotrigine plasma levels. Sertraline can increase lamotrigine plasma levels twofold. Acetaminophen, olanzapine, rifampicin, and ritonavir can decrease lamotrigine plasma levels by ~20% [32,33].

14.7.10 Levetiracetam

Levetiracetam undergoes minimal metabolism with ~30% of the dose metabolized by hydrolysis to a deaminated metabolite. This metabolism is independent of the hepatic CYP system and is via a type B esterase enzyme located in whole blood. The metabolites of levetiracetam are not pharmacologically active.

14.7.10.1 Effect of Levetiracetam on Other Drugs. Levetiracetam does not undergo hepatic metabolism but undergoes minimal metabolism in whole blood [34]. Consequently, it is not amenable to interference. To date, levetiracetam has not been associated with any clinically significant metabolic interactions affecting other drugs [35,36].

14.7.10.2 Effect of Other Drugs on Levetiracetam. To date, the nonhepatic metabolism of levetiracetam has not been affected by other drugs, and thus, the drug is not associated with any clinically significant metabolic interactions [35,36].

14.7.11 Oxcarbazepine

Oxcarbazepine is rapidly metabolized in the liver to its pharmacologically active metabolite, 10-hydroxycarbazepine (also known as *licarbazepine*), by stereoselective biotransformation mediated by cytosolic arylketone reductase. 10-Hydroxycarbazepine comprises of a racemic mixture of 80% S-form (active) and 20% R-form (inactive). 10-Hydroxycarbazepine is subsequently primarily metabolized by conjugation with glucuronic acid. Minor amounts (4% of dose) of 10-hydroxycarbazepine are oxidized to an inactive 10,11-dihydroxy metabolite.

Metabolites (other than 10-hydroxycarbazepine) are not pharmacologically active [37,38]. Overall, oxcarbazepine has a low propensity for metabolic interactions.

14.7.11.1 Effect of Oxcarbazepine on Other Drugs. *In vitro* studies show that both oxcarbazepine and 10-hydroxycarbazepine have little or no capacity to inhibit the CYP1A, CYP2D, and CYP2E families. However, CYP2C19 is significantly inhibited by oxcarbazepine and consequently can increase plasma levels of phenobarbital and phenytoin by 14% and 40%, respectively [39]. Oxcarbazepine can induce the metabolism of carbamazepine and topiramate and decrease their plasma levels. Additionally, oxcarbazepine induces the metabolism of lamotrigine, via an effect on UGTs, and decreases lamotrigine plasma levels by 29% [40]. Felodipine plasma levels can decrease by 28% when oxcarbazepine is administered concurrently [41]. Oxcarbazepine can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2).

14.7.11.2 Effect of Other Drugs on Oxcarbazepine. Because oxcarbazepine is metabolized by noninducible ketoreductases, its disposition is largely unaffected by CYP inducers. However, coadministration with carbamazepine, phenobarbital, phenytoin, and primidone can increase the clearance of 10-hydroxycarbazepine and decrease its plasma levels [42]. Additionally, verapamil can decrease 10-hydroxycarbazepine plasma levels, while viloxazine can increase its plasma levels [43,44].

14.7.12 Phenobarbital

Phenobarbital undergoes significant metabolism in the liver to two major metabolites, *p*-hydroxyphenobarbital (~20–30% of administered dose), which partially (50%) undergoes sequential metabolism to a glucuronic acid conjugate, and 9-D-glucopyranosylphenobarbital (~25–30% of administered dose), a nitrogen

glucosidation conjugate. CYP2C9 plays a major role in the metabolism of phenobarbital to *p*-hydroxyphenobarbital, with minor metabolism by CYP2C19 and CYP2E1. The identity of the UGT enzyme responsible for the formation of 9- β -glucopyranosylphenobarbital is unknown. The metabolites of phenobarbital are not pharmacologically active. Overall, phenobarbital has a substantial propensity for metabolic interactions and acts as an inducer of metabolism.

14.7.12.1 Effect of Phenobarbital on Other Drugs. Phenobarbital induces the metabolism of many drugs, particularly those metabolized by CYP2C and CYP3A subfamilies and UGTs. The time course of induction (and deinduction) primarily depends on the half-life of phenobarbital, which is long (70–140 h). Consequently, induction typically begins within approximately a week, with maximum induction occurring two to three weeks after initiation of phenobarbital therapy. Phenobarbital can increase the clearance and decrease the plasma levels of many AEDs including carbamazepine, clobazam, clonazepam, diazepam, ethosuximide, felbamate, lamotrigine, midazolam, oxcarbazepine, phenytoin, rufinamide, stiripentol, tiagabine, topiramate, valproic acid, and zonisamide (Table 14.1). Phenobarbital also induces the metabolism of many non-AED drugs (Table 14.3), the magnitude of which is particularly substantial for many drugs. Phenobarbital can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2) [6].

14.7.12.2 Effect of Other Drugs on Phenobarbital. Inhibitors of CYP2C9 should have an effect on the metabolism of phenobarbital; however, the effect is small because only ~20% of metabolism occurs through this pathway. Felbamate, oxcarbazepine, phenytoin, rufinamide, stiripentol, and valproic acid can decrease the clearance of phenobarbital and increase its plasma levels. The effect of valproic acid is particularly profound because valproic acid inhibits not only CYP2C9-dependent hydroxylation but also phenobarbital glucuronidation, with phenobarbital plasma levels increasing by ~100%. Additionally, chloramphenicol, dicoumarol, and propoxyphene can increase phenobarbital plasma levels [6].

14.7.13 Phenytoin

Phenytoin undergoes extensive metabolism in the liver by hydroxylation to various metabolites, the principal metabolites being 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (*p*-HPPH; 67–88%) and a dihydrodiol derivative (7–11%). The isoenzymes responsible for the hydroxylation of phenytoin are CYP2C9 (~80%) and CYP2C19 (~20%). In excess of 60% of *p*-HPPH is subsequently glucuronidated and excreted in urine. The metabolites of phenytoin are not pharmacologically active. Overall, phenytoin has a substantial propensity for metabolic interactions and acts as an inducer of metabolism.

14.7.13.1 Effect of Phenytoin on Other Drugs. Phenytoin increases the metabolism of drugs that are metabolized by CYP2C and CYP3A subfamilies and UGT enzymes. Consequently, phenytoin can decrease plasma levels of many AEDs including carbamazepine, clobazam, clonazepam, ethosuximide, felbamate, lamotrigine, oxcarbazepine, phenobarbital, primidone, rufinamide, stiripentol, tiagabine, topiramate, valproic acid, and zonisamide (Table 14.1) [6].

Phenytoin also induces the metabolism of many non-AED drugs and decreases their plasma levels (Table 14.3). The magnitude of which is particularly substantial for many drugs. Phenytoin can increase plasma levels of chloramphenicol [6] and can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2) [6].

14.7.13.2 Effect of Other Drugs on Phenytoin. Carbamazepine and phenobarbital can increase the clearance of phenytoin and decrease its plasma levels. Carbamazepine, in addition, can inhibit phenytoin metabolism and increase plasma phenytoin levels. The AEDs clobazam, felbamate, oxcarbazepine, phenobarbital, rufinamide, stiripentol, topiramate, and zonisamide can decrease the clearance of phenytoin and increase its plasma levels (Table 14.1).

Phenytoin metabolism can be inhibited by a variety of non-AED drugs, resulting in increases in phenytoin plasma levels. Such drugs include allopurinol, amiodarone, azapropazone, bleomycin, chlorphenamine, clarithromycin, chloramphenicol, cimetidine, clinafloxacin, cotrimoxazole, disulfiram, dextropropoxyphene (propoxyphene), dicoumarol, diltiazem, doxifluridine, erythromycin, esomeprazole, fenyramidol, fluconazole, 5-fluorouracil, fluoxetine, fluvoxamine, imipramine, indinavir, isoniazid, itraconazole, methylphenidate, metronidazole, miconazole, nelfinavir, nifedipine, omeprazole, risperidone, ritonavir, saquinavir, sertraline, sulfinpyrazone, tamoxifen, tegafur, ticlopidine, trazodone, verapamil, viloxazine, and voriconazole (Table 14.3) [6].

Phenytoin metabolism can be induced by a variety of non-AED drugs, resulting in decreases in its plasma levels. These include drugs such as acyclovir, carboplatin, carmustine, cisplatin, dexamethasone, diazoxide, etoposide, loxapine, methotrexate, rifampicin, St. John's wort, sucralfate, theophylline, and vinblastine [6].

14.7.14 Pregabalin

Pregabalin is not metabolized, is excreted unchanged in urine, and, as such, is neither a hepatic enzyme inducer nor an inhibitor. To date, pregabalin has not been associated with any clinically significant metabolic interactions.

14.7.15 Primidone

Primidone is metabolized in the liver to two primary metabolites, namely, phenobarbital and phenylethylmalonamide (PEMA). Phenobarbital subsequently undergoes metabolism to two metabolites, *p*-hydroxyphenobarbital and 9-D-glucopyranosylphenobarbital. PEMA is pharmacologically active but has a much lower potency than primidone and phenobarbital. Overall, primidone has a substantial propensity for metabolic interactions and acts as an inducer of metabolism.

14.7.15.1 Effect of Primidone on Other Drugs. Because phenobarbital is invariably present during long-term primidone treatment, all the effects of phenobarbital on other drugs described previously for phenobarbital can be expected with primidone, and all the interactions affecting phenobarbital will also affect the phenobarbital derived from primidone (for further details, see Section 14.7.12).

14.7.15.2 Effect of Other Drugs on Primidone. Phenytoin and carbamazepine can accelerate the conversion of primidone to phenobarbital, which results in decreased primidone plasma levels and increased phenobarbital levels (for further details, see Section 14.7.12).

14.7.16 Rufinamide

Rufinamide is metabolized in the liver, primarily by hydrolysis which is not CYP dependent, to CGP 47292, which is subsequently excreted in urine (~70%) and feces (~9%). Approximately 7% is excreted in urine as minor acyl-glucuronide metabolites of CGP 47292. The metabolites of rufinamide are not pharmacologically active.

Overall, rufinamide has a minimal propensity for metabolic interactions.

14.7.16.1 Effect of Rufinamide on Other Drugs. Rufinamide can decrease plasma levels of carbamazepine and lamotrigine, but increases plasma levels of phenobarbital and phenytoin (Table 14.1). In contrast, rufinamide can decrease plasma levels of triazolam [45–47]. Rufinamide can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2).

14.7.16.2 Effect of Other Drugs on Rufinamide. Carbamazepine, phenobarbital, phenytoin, primidone, and vigabatrin can increase the clearance of rufinamide and decrease rufinamide plasma levels. In contrast, valproic acid can decrease the clearance of rufinamide and increase its plasma levels

To date, there have been no reports of other drugs affecting the clearance of rufinamide and affecting rufinamide plasma levels [45–47].

14.7.17 Stiripentol

Stiripentol is metabolized in the liver, primarily by desmethylation and glucuronidation, to 13 different metabolites. Precise identification of enzymes involved in its metabolism is not known, but the principal enzymes are considered to be CYP1A2, CYP2C19, and CYP3A4. The metabolites of stiripentol are not considered to be pharmacologically active. Overall, stiripentol has a substantial propensity for metabolic interactions and acts as an inhibitor of metabolism.

14.7.17.1 Effect of Stiripentol on Other Drugs. Because stiripentol has limited use in the management of epilepsy, its exact interaction profile has not been identified. However, because stiripentol is a potent inhibitor of CYP2C19, CYP3A4, and CYP2D6, caution needs to be exercised if clinical circumstances require combining stiripentol with drugs that are metabolized by these isoenzymes [e.g., citalopram, omeprazole (CYP2C19); chlorpheniramine, calcium channel blockers, statins, codeine (CYP3A4); propranolol, fluoxetine, sertraline, haloperidol, tramadol (CYP2D6)]. Stiripentol can inhibit the metabolism of carbamazepine, phenobarbital, valproic acid, and clobazam and its pharmacologically active metabolite *N*-desmethyclobazam and increase their plasma levels. The effect on clobazam and *N*-desmethyclobazam is particularly profound with levels increasing up to fourfold [25,26,48].

14.7.17.2 Effect of Other Drugs on Stiripentol. Carbamazepine, phenobarbital, phenytoin, and primidone can increase the clearance of stiripentol and decrease stiripentol plasma levels. To date, there have been no reports of other drugs affecting the clearance and plasma levels of stiripentol [25,26,48].

14.7.18 Tiagabine

Tiagabine is metabolized in the liver, primarily by CYP3A4, to two 5-oxo-tiagabine isomers (E5 and Z-5) that represent ~60% of metabolism. The remaining 40% of metabolites have yet to be identified [49]. The metabolites of tiagabine are not pharmacologically active. Tiagabine is neither an enzyme inducer nor an enzyme inhibitor, and therefore, its propensity to interact is minimal.

14.7.18.1 Effect of Tiagabine on Other Drugs. Tiagabine can decrease valproic acid plasma levels through an unknown mechanism (Table 14.1) [50]. To date, there have been no reports of tiagabine affecting the clearance and plasma levels of other non-AED drugs. The metabolism of oral contraceptives is unaffected by tiagabine, and therefore, it does not compromise contraceptive control (Table 14.2).

14.7.18.2 Effect of Other Drugs on Tiagabine. Carbamazepine, phenobarbital, phenytoin, and primidone can increase the clearance of tiagabine by 50–60%, via an action on CYP3A4, and decrease tiagabine plasma levels [51].

14.7.19 Topiramate

Topiramate is not extensively metabolized in patients on monotherapy or in patients not prescribed enzyme-inducing drugs, and typically, 40–50% of a topiramate dose is excreted unchanged via the kidneys. However, in the presence of enzyme-inducing drugs, metabolism becomes an important feature of the elimination of topiramate and this value is doubled. Metabolites thus far identified include two hydroxy and two diol metabolites, as well as several glucuronide conjugates, none of which constitutes more than 5% of an administered dose. Although the specific CYP isoenzymes for the metabolism of topiramate have not been identified, it is evident that isoenzymes induced by carbamazepine and phenytoin play a major role [52]. The metabolites of topiramate are not pharmacologically active. Overall, topiramate has a low propensity for metabolic interactions, with its metabolism both induced and inhibited by other drugs.

14.7.19.1 Effect of Topiramate on Other Drugs. Topiramate is a weak inducer of CYP enzymes and weakly inhibits CYP2C19 [53]. Topiramate can decrease the clearance of phenytoin and increase phenytoin plasma levels, while it can increase the clearance of valproic acid and decrease valproic acid plasma level. With regard to non-AED drugs, topiramate can increase the clearance and decrease the plasma levels of digoxin, glibenclamide, pioglitazone, risperidone, and sumatriptan, while it can decrease the clearance and increase the plasma levels of amitriptyline, haloperidol, hydrochlorothiazide, lithium, and metformin [54,55]. Topiramate can induce the metabolism of the estrogen component of an oral contraceptive pill and therefore may reduce the effectiveness of oral contraception (Table 14.2).

14.7.19.2 Effect of Other Drugs on Topiramate. Carbamazepine, oxcarbazepine, phenobarbital, phenytoin, primidone, and valproic acid can increase the clearance of topiramate and decrease its plasma levels (Table 14.1) [56,57]. Amitriptyline, lithium, metformin, propranolol, and sumatriptan can decrease the clearance of topiramate and increase its plasma levels [6].

14.7.20 Valproic Acid

The metabolism of valproic acid in the liver is extensive and complex, in that it involves multiple metabolic pathways including O-glucuronidation, β oxidation, ω oxidation hydroxylation, ketone formation, and desaturation. To date, in excess of 25 metabolites have been identified. Valproic acid glucuronide and 3-oxo-valproic acid are by far the most abundant metabolites (~40% and 33% of an administered dose, respectively). Hydroxylation to form 4-ene-valproic acid and other metabolites is via the action of CYP2A6, CYP2C9, CYP2C19, and CYP2B6 isoenzymes, while O-glucuronidation is mediated by UGT1A3 and UGT2B7 isoforms. Some metabolites are pharmacologically active; 2-ene-valproic acid and 4-ene-valproic acid have anticonvulsant activity that is similar in potency to that of valproic acid itself. Overall, valproic acid has a substantial propensity for metabolic interactions and acts as an inhibitor of metabolism.

14.7.20.1 Effect of Valproic Acid on Other Drugs. Valproic acid is a broad-spectrum inhibitor of hepatic metabolism, including inhibition of CYP2C9, CYP2C19, UGT1A4, and epoxide hydrolase [58]. Additionally, its metabolism can be both induced and inhibited. Valproic acid can decrease the clearance and increase plasma levels of carbamazepine epoxide, ethosuximide, felbamate, lamotrigine, lorazepam, midazolam, phenobarbital, and rufinamide (Table 14.1). Valproic acid can also increase the clearance and decrease plasma levels of topiramate and zonisamide. Of these interactions, three stand out: the inhibition of the metabolism of phenobarbital and lamotrigine and that of the active metabolite of carbamazepine, carbamazepine epoxide. During comedication with phenobarbital, phenobarbital plasma levels increase over two to three weeks by about 30–50% in most patients, but in some patients, the increase can be twofold. Inhibition of lamotrigine metabolism results in a twofold increase in lamotrigine plasma levels and the inhibitory effect is maximal at the relatively low valproate dose of 500 mg/day [59]. The particular significance of this interaction relates to the risk of lamotrigine-induced skin rashes, which is dependent on the rate of rise in plasma lamotrigine levels. Valproic acid inhibition of epoxide hydrolase results in an increase in plasma carbamazepine epoxide levels. The significance of this interaction is based on the fact that carbamazepine toxicity occurs in the absence of an effect on plasma carbamazepine levels [21].

With regard to non-AED drugs, valproic acid can decrease the clearance and increase the plasma level of amitriptyline, aripiprazole, clomipramine, chlorpromazine, lopinavir, naproxen, nimodipine, nortriptyline, paroxetine, and zidovudine [6,60]. The metabolism of oral contraceptives is unaffected by valproic acid, and therefore it does not compromise contraceptive control (Table 14.2).

14.7.20.2 Effect of Other Drugs on Valproic Acid. Carbamazepine, lamotrigine, phenobarbital, phenytoin, primidone, and topiramate can increase the clearance of valproic acid and decrease valproic acid plasma levels (Table 14.1).

In contrast, clobazam, felbamate, and stiripentol can decrease the clearance of valproic acid and increase valproic acid plasma levels. The effect of felbamate is via inhibition of the β oxidation pathway. With regard to non-AED drugs, amikacin, diflunisal, meropenem, naproxen, paripenem, rifampicin, and ritonavir can increase the clearance and decrease valproic acid plasma levels. In contrast, chlorpromazine, fluoxetine, isoniazid, and sertraline can decrease the clearance and increase valproic acid plasma levels [6,60].

14.7.21 Vigabatrin

Vigabatrin is not metabolized, is excreted unchanged in urine, and, as such, is neither a hepatic enzyme inducer nor an inhibitor. To date, vigabatrin has not been associated with any clinically significant metabolic interactions [6,60].

14.7.22 Zonisamide

Zonisamide undergoes acetylation to form *N*-acetyl zonisamide and reduction to form 2-sulfamoylacetylphenol, the latter being subsequently glucuronidated. The reduction of zonisamide to 2-sulfamoylacetylphenol is mediated by the CYP3A4 isoenzyme [61]. Metabolites are not pharmacologically active. Overall, zonisamide has a low propensity for metabolic interactions.

14.7.22.1 Effect of Zonisamide on Other Drugs. Although zonisamide is not an enzyme inducer, it appears to act as a weak enzyme inhibitor. *In vitro* studies on the inhibitory characteristics of zonisamide showed that drugs metabolized by CYP3A4, CYP1A2, or CYP2D6 should not be affected, but drugs metabolized by CYP2A6, CYP2C9, CYP2E1, and CYP2C19 may be slightly inhibited [62]. A 16% increase in phenytoin plasma levels can be expected in patients coprescribed with zonisamide [63], consequent to an inhibition of CYP2C19, while carbamazepine plasma levels have been reported to both increase and decrease (Table 14.1) [64]. The metabolism of oral contraceptives is unaffected by zonisamide, and therefore, it does not compromise contraceptive control (Table 14.2). To date, there have been no reports of zonisamide affecting the clearance and plasma levels of non-AED drugs.

14.7.22.2 Effect of Other Drugs on Zonisamide. Carbamazepine, phenobarbital, phenytoin, primidone, and valproic acid can increase the clearance of zonisamide and decrease its plasma levels (Table 14.1) [65–67]. Lamotrigine can increase zonisamide plasma levels twofold [68], while risperidone can decrease zonisamide plasma levels [69].

14.8 ANTIEPILEPTIC DRUGS CURRENTLY UNDERGOING DEVELOPMENT

14.8.1 Brivaracetam

Brivaracetam undergoes metabolism, primarily through hydrolysis and secondarily through hydroxylation mediated by CYP2C9, CYP2C19, CYP3A4, and to a negligible

extent by CYP2B6 and CYP2C8. Enzyme-inducing AEDs and rifampicin decrease plasma brivaracetam levels, while brivaracetam can increase the plasma levels of phenytoin and carbamazepine epoxide [70].

14.8.2 Ganaxolone

Ganaxolone is metabolized, primarily by CYP3A4/3A5, to yet unknown metabolites, which are eliminated from plasma at a rate three to six times faster than the terminal half-life of ganaxolone. Preliminary trials have not identified significant drug interactions with concomitant AEDs [71].

14.8.3 Seletacetam

Seletacetam is eliminated by hydrolysis and is excreted in urine. Its primary metabolite is an acidic inactive metabolite (ucb-101596-1), the concentration of which in plasma is ~10-fold lower than that of the parent compound. Two additional minor metabolites have been identified in urine. Overall, 25% of a seletacetam dose is excreted in the unchanged form [72]. On the basis of *in vitro* data, there is a low potential for interactions involving seletacetam. The drug interaction profile of seletacetam in the clinical setting is at present unknown.

14.8.4 Talampanel

Although its metabolic pathways have not been completely characterized in man, acetylation appears to occur, where talampanel is converted to *N*-acetyl-talampanel by hepatic *N*-acetyltransferase 2. This metabolic route is not major, but there appears to be significant interpatient differences in plasma concentrations of *N*-acetyl-talampanel, which is pharmacologically active and may also contribute to adverse effects in some patients. In an *in vitro* setting, talampanel has been shown to be an irreversible inhibitor of the CYP3A, and consequently, it would be anticipated that it may inhibit the metabolism of CYP3A substrates such as carbamazepine. Indeed, carbamazepine plasma levels are elevated during carbamazepine and talampanel coadministration. Also, there is evidence to suggest that talampanel inhibits valproic acid metabolism, resulting in increased plasma valproic acid levels. In patients with epilepsy, the clearance of talampanel is enhanced by enzyme-inducing AEDs such as carbamazepine and phenytoin, so that its half-life is reduced to about 3 h, while valproic acid does not appear to affect talampanel clearance [73].

14.8.5 Tonabersat

Tonabersat is highly bound to plasma proteins (98.2%) and undergoes metabolism by cytosolic carbonyl reductase enzymes to a reduced ketone, with negligible amounts excreted in urine unchanged. The primary metabolite is detectable in plasma. Acetyl hydroxylation via the CYP3A family of enzymes accounts for a minor hydroxyl metabolite [71]. The drug interaction profile of tonabersat in the clinical setting is at present unknown.

14.8.6 Valrocecimide

Approximately 10–20% of an administered dose is excreted unchanged in urine, and 40% is excreted in the form of valproyl glycine. Urinary valproic acid accounts for 4–6% of an administered valrocecimide dose. *In vitro* studies using CYP isoenzymes indicate that significant drug interactions with other AEDs would not be anticipated. Nevertheless, higher valrocecimide clearance and shorter half-life values were observed in patients receiving enzyme-inducing AEDs [74].

14.9 CONCLUSIONS AND FUTURE PERSPECTIVES

As a class of drugs, the AEDs are associated with more pharmacokinetic (metabolic) interactions than any other therapeutic drug class. The reason for this is that the older first-generation AEDs (carbamazepine, phenobarbital, phenytoin, and valproic acid) are widely prescribed and commonly used as first-line therapy. Additionally, these AEDs have a substantial ability to induce and/or inhibit hepatic metabolism, and consequently, their propensity to interact is substantial [4,5]. Furthermore, these AEDs, along with some of the newer AEDs (e.g., eslicarbazepine acetate, felbamate, lamotrigine, oxcarbazepine, tiagabine, topiramate, and zonisamide), are susceptible to inhibition and induction of their own metabolism [75]. Of the new AEDs, those that are renally excreted (e.g., gabapentin, levetiracetam, pregabalin, and vigabatrin) have minimal or no potential to interact, while those that undergo minimal/moderate metabolism with non-CYP- and non-UGT-dependent isoenzyme systems (levetiracetam, lacosamide) similarly are not susceptible to interference [75]. Finally, there are more new AEDs under development, and on the basis of available data, it would appear that the general trend of the developing AEDs that are associated with a reduced propensity for pharmacokinetic (metabolic) interactions continues [71].

From a clinical therapeutic viewpoint, AED metabolic interactions are best avoided by the use of drugs that are not potent CYP inhibitors or inducers and are not readily inhibited by other drugs. In reality, drug interactions caused by mutual inhibition are almost inevitable because CYP-mediated metabolism represents a major route of elimination of many drugs and because the same CYP enzymes can metabolize numerous drugs. Whenever polytherapy with known interacting drugs is contemplated, it is best practice to monitor blood levels of the affected drug before and after the introduction of the interacting drug [76]. Thus, a graded therapeutic adjustment can be undertaken so as to prevent unnecessary toxicity or seizure breakthrough consequent to the interaction.

15.1 SUMMARY

Oral chemotherapeutic agents have been available for decades, and there has been an accelerated expansion in their development during the recent decade. Oral chemotherapeutic agents offer obvious advantages in terms of convenient and noninvasive administration, flexibility and adaptability of dosing, as well as financial and staff time savings. Compared to intravenous agents, oral chemotherapeutic agents generally exhibit substantial interindividual pharmacokinetic variability. Many factors contribute to this variability, including physiological, pathological, environmental, and genetic factors. Unique to oral agents, poor and variable bioavailability is one important source of the interindividual pharmacokinetic variability. This chapter discusses the factors influencing bioavailability of oral chemotherapeutic agents, with focus on the first-pass metabolism by cytochrome P450 3A4 (CYP3A4), intestinal efflux by ABCB1 transporter, and other factors such as concomitant administration of antacid medications, food effect, and surgery. Oral chemotherapeutic agents can be classified as traditional cytotoxic agents and novel molecularly targeted agents, hormonal agents, and immunomodulating agents. Each class of agents is unique with regard to its mechanisms of action, pharmacokinetics, mechanisms of drug resistance, and clinical use. This chapter provides an overview of the major classes of oral chemotherapeutic agents, particularly highlighting examples whereby genetic variations in the genes involved in the drug disposition or drug–target interaction influence the pharmacokinetics and/or response.

15.2 INTRODUCTION

Cancer chemotherapy has traditionally been dominated by intravenous drug administration. However, oral chemotherapeutic agents provide obvious advantages in terms of convenient and noninvasive administration, flexibility and adaptability of dosing, and financial and staff time savings [1]. The use of oral chemotherapeutic agents has been increased, especially in the recent decade. Modern cancer chemotherapy was introduced in the 1940s with the use of intravenous nitrogen mustard for the treatment of hematological malignancies [2]. In the 1950s, several oral chemotherapeutic agents (e.g., melphalan, busulfan, and chlorambucil) were investigated for their efficacy in cancer treatment [3–6], and the first oral chemotherapeutic agent, mercaptopurine, was approved by the United States Food & Drug Administration (FDA) in 1953. By the 1970s, many other oral chemotherapeutic agents were approved (e.g., procarbazine in 1969, lomustine in 1976, and tamoxifen in 1977). Yet, oral chemotherapy has not become popular as an oncologic drug delivery route until the recent decade, when a number of orally bioavailable small molecule kinase inhibitors (e.g., imatinib, gefitinib, erlotinib, sorafenib, sunitinib, etc.) have been developed and proved effective for the treatment of certain types of tumors in clinical settings. According to a 2008 National Comprehensive Cancer Network (NCCN) Task Force Report, it is estimated that one-fourth of the 400 antineoplastic agents currently in the pipeline are planned as oral drugs [7] and more than 20 oral chemotherapeutic agents have been currently approved by the FDA for the treatment of cancer [8].

Compared to intravenous agents, oral chemotherapeutic agents generally exhibit substantial interindividual pharmacokinetic variability. This variability can lead to therapeutic failure or severe toxicity. Multiple factors contribute to variations in the pharmacokinetics and response of chemotherapeutic agents. These include drug-specific factors (e.g., dosage form or formulation, dose, and schedule), patient's demographic (e.g., age, race, and sex), physiological (e.g., body size and composition) and pathological factors (e.g., disease status and organ functions), as well as environmental (e.g., interactions with food, environmental toxins, and other drugs) and genetic factors (e.g., genetic polymorphisms in the genes encoding drug-metabolizing enzymes, transporters, and drug targets). Unique to oral chemotherapeutic agents, absorption is the prerequisite for the systemic exposure and activity. Poor and variable oral bioavailability is one important source of the interindividual pharmacokinetic variability of oral agents. In this chapter, we discuss the factors influencing bioavailability of oral chemotherapeutic agents, with focus on first-pass metabolism, intestinal ABCB1 efflux, and other factors such as concomitant administration of antacid medications, food effect, and surgery.

Broadly, oral chemotherapeutic agents can be classified as traditional cytotoxic agents (e.g., alkylating agents, antimetabolites, and plant alkyls), novel molecularly targeted agents (e.g., small molecule TKIs, mTOR inhibitors, and HDAC inhibitors), hormonal agents (e.g., tamoxifen, letrozole, and anastrozole), and immune-modulating agents (e.g., thalidomide and lenalidomide). Traditional cytotoxic agents cause cancer cell death or cell cycle arrest by inducing a diverse spectrum of toxic DNA lesions (e.g., base damage, bulky adducts, replication lesions, DNA cross-links, single-strand breaks, and double-strand breaks) or interfering with cell division, a multiphase process involving the synthesis of nucleic acids, RNA, and DNA and nuclear division (i.e., mitosis). Molecularly targeted agents have emerged as a new generation of cancer treatment in the recent decade. Their mechanisms of action and toxicity profiles

differ from those of traditional cytotoxic agents. In contrast to traditional agents that act on rapidly dividing cells, including cancer cells, as well as normal tissue cells, novel molecularly targeted agents are designed to interfere with specific targets, which are usually located within tumor cells or surrounding cells. Therefore, novel molecularly targeted agents have a relative higher specificity toward tumor cells, providing a broader therapeutic window with less toxicity. In addition, some drugs that modulate tumor cell behavior or environment without directly attacking those cells are used for the treatment of cancer. Hormonal agents and immune-modulating agents fall into this category. Each class of agents is unique with regard to its mechanisms of action, pharmacokinetics, mechanisms of resistance, and clinical use. In this chapter, we review the major classes of oral chemotherapeutic agents, from a pharmacological and clinical perspective.

15.3 FACTORS INFLUENCING BIOAVAILABILITY OF ORAL CHEMOTHERAPEUTIC AGENTS

In general, the absorption of a solid drug from the gastrointestinal (GI) tract involves the following four steps: (i) gastric emptying and small intestinal transit flow to deliver the drug to its absorption site, (ii) dissolution of the solid drug into solution available for absorption, (iii) permeation of the dissolved drug through the GI membrane, and (iv) movement of the drug through the gut wall and liver before entering the general circulation [9]. Many physical, anatomic, and physiologic factors may influence the overall rate and extent of drug absorption from the GI tract. Included among them are the physicochemical properties of the drug (e.g., solubility, lipophilicity, and stability), the properties of the formulation (e.g., disintegration time, dissolution rate, and stability), and physiological features of the patient (e.g., the nature of the membrane, gastric emptying and intestinal transit, blood perfusion, and pH in the GI tract) [10]. Notably, incomplete dissolution, first-pass intestinal and hepatic metabolism, and efflux by transporters (e.g., ABCB1) in the gut lumen are the common causes of poor and variable oral bioavailability of chemotherapeutic agents.

15.3.1 First-Pass Metabolism

First-pass metabolism in the gut wall and liver before an oral drug enters systemic circulation is one major factor causing low oral bioavailability of some chemotherapeutic agents such as 5-fluorouracil (5-FU), doxorubicin, and docetaxel. The human cytochrome P450 (CYP) superfamily represents the most important system responsible for catalyzing the oxidation of a large number of drugs. Three subfamilies of CYPs, including CYP1, CYP2, and CYP3, contribute to the oxidative metabolism of more than 90% of clinically used drugs. CYP3A4 has the highest abundance in human liver and intestine, contributing to the first-pass metabolism and systemic clearance of many chemotherapeutic agents (e.g., cyclophosphamide, etoposide, ifosfamide, paclitaxel, docetaxel, tamoxifen, vinblastine, gefitinib, erlotinib, and imatinib).

There is significant interindividual variability in the expression/activity of CYP3A4. It has been reported that hepatic and intestinal CYP3A4 expressions and activities vary at least 10- and 6-folds, respectively, among individuals [11,12]. This substantial heterogeneity could attribute to large interindividual variation in the first-pass metabolism

and systemic clearance of oral chemotherapeutic agents that are CYP3A4 substrates. An *in vivo* phenotypic probe for CYP3A4 may have utility for prediction of the systemic exposure and selection of the dose for CYP3A substrate drugs. Commonly used CYP3A4 phenotypic probe drugs include midazolam, erythromycin, cortisol, and dexamethasone. The apparent clearance of oral midazolam is a useful indicator of combined hepatic and intestinal CYP3A4/5 activity because midazolam, after its oral administration, undergoes substantial metabolism by CYP3A4/5 in the intestine and liver [13]. A prospective study in patients with cancer demonstrates that midazolam oral clearance accounts for a substantial (~40%) portion of the interindividual variability of gefitinib oral clearance, implicating that oral midazolam test has the potential for prediction of systemic exposure and optimization of treatment with gefitinib and other TKIs that are predominantly metabolized by CYP3A4 [14].

While over 28 single nucleotide polymorphisms (SNPs) have been identified in human *CYP3A4* gene, genetic polymorphisms of *CYP3A4* account insignificantly for the interindividual variability of CYP3A4 activity *in vivo*. The substantial variation in CYP3A4 activity could be caused by induction or inhibition of CYP3A4 on exposure to a wide variety of drugs or chemicals. The list of representative CYP3A4 inducers and inhibitors is presented in Table 15.1. Note that CYP3A4 is particularly susceptible to enzyme inducers. For an oral chemotherapeutic agent that is a CYP3A4 substrate, concomitant administration of a CYP3A4 inducer can markedly reduce its oral bioavailability and systemic exposure, whereas a reverse pattern may be seen with concomitant administration of a CYP3A4 inhibitor. For example, a study in 224 patients with glioblastoma showed that the mean trough level of imatinib was reduced up to 2.9-fold in patients receiving daily oral imatinib 600 mg in combination with CYP3A4-inducing antiepileptic drugs (i.e., carbamazepine, phenytoin, and oxcarbazepine) compared to those not taking CYP3A4-inducing antiepileptic drugs [15]. Another example is represented by lapatinib, which is predominantly metabolized by CYP3A4. Concomitant administration of strong CYP3A4 inhibitors (e.g., ketoconazole) or inducers (e.g., carbamazepine) significantly alters lapatinib plasma concentrations. Therefore in the package insert, dose adjustment of lapatinib is recommended for patients who must receive concomitant strong inhibitors or inducers of CYP3A4.

It is worth noting that the oral administration of some chemotherapeutic agents such as paclitaxel and docetaxel is hampered by their low oral bioavailability, partly due to extensive first-pass metabolism by CYP3A4. Pharmacologic inhibition of CYP3A4 could substantially enhance oral bioavailability of such agents. For example, preclinical studies demonstrated that inhibition of CYP3A4 with ritonavir (a CYP3A4 inhibitor) increased the oral bioavailability of oral docetaxel by 50-fold in both wild-type and ABCB1 knockout mice [16]. Consistently, a clinical study in patients with solid tumors demonstrated that the oral bioavailability of docetaxel was 131% when it was administered concomitantly with ritonavir, suggesting that ritonavir inhibited both presystemic (first-pass) and systemic metabolism of docetaxel [17]. This example indicates that CYP3A4 modulation has clinical implication for improving bioavailability of oral chemotherapeutic agents that undergo extensive first-pass metabolism by CYP3A4.

TABLE 15.1 Oral Chemotherapeutic Agents that are Substrates, Representative Inhibitors, and Inducers of CYP3A4

Substrates (Oral Chemotherapeutic Agents)	CYP3A4 Inhibitors	CYP3A4 Inducers
Capecitabine	Amiodarone	Dexamethasone
Cyclophosphamide	Anastrozole	Efavirenz
Dasatinib	Aprepitant	Modafinil
Erlotinib	Azole antifungal (fluconazole, itraconazole, ketoconazole, miconazole, posaconazole, voriconazole)	Nafcillin
Etoposide	Clarithromycin, erythromycin	Nevirapine
Everolimus	Cyclosporine	Phenobarbital
Exemestane	Cyclophosphamide	Phenytoin, Fosphenytoin
Gefitinib	Dasatinib	Rifampin
Imatinib	Diltiazem	St. John's wort
Lapatinib	Everolimus	—
Letrozole	Fluoxetine	—
Nilotinib	Grapefruit juice	—
Pazopanib	HIV protease inhibitors (atazanavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir)	—
Sunitinib	Isoniazid	—
Sorafenib	Imatinib	—
Tamoxifen	Lapatinib	—
—	Nilotinib	—
—	Sunitinib	—
—	Sorafenib	—
—	Verapamil	—
—	Vorinostat	—

15.3.2 Intestinal ABCB1 Efflux

In addition to drug-metabolizing enzymes, uptake and efflux transporters that facilitate the movement of drugs in or out of the cell are important determinants of drug disposition and response. Broadly, drug transporters are classified into two families, namely efflux transporters of the ATP-binding cassette (ABC) family and uptake transporters of the solute carrier (SLC) family. These transporters play crucial roles in the intestinal absorption, biliary excretion, renal excretion, and tissue/cellular penetration of a wide variety of therapeutic drugs [18]. The ABC transporters are responsible for the transport of diverse substrates out of the cell using adenosine-5' triphosphate (ATP) as an energy source. In the ABC transporter family, ABCB1 has been well characterized for its roles in limiting oral bioavailability of the substrate drugs. The *ABCB1* gene, also named as the multidrug resistance 1 (*MDR1*) gene, encodes a polypeptide (P-glycoprotein) that has two halves, each containing six hydrophobic transmembrane

domains and an ATP-binding domain. ABCB1, located on the apical or luminal surface of the epithelial cells, functions as an efflux transporter in restricting intestinal absorption, facilitating hepatobiliary excretion and renal excretion, and protecting the brain and fetus from xenobiotics. In addition, ABCB1 overexpression in cancer cells is implicated in multidrug resistance to chemotherapeutic agents [19].

There is evidence that intestinal ABCB1 limits the intestinal absorption of some chemotherapeutic agents such as paclitaxel, docetaxel, and vinblastine [20,21]. It has been demonstrated that the coadministration of oral ABCB1 inhibitors significantly increases intestinal absorption of taxanes and topotecan [22,23]. Thus, the use of potent and specific ABCB1 inhibitors has potential in improving the bioavailability of oral chemotherapeutic agents that are ABCB1 substrates. A clinical proof-of-concept study in patients with advanced solid malignancies demonstrated that oral docetaxel achieved an average bioavailability of 90% when it was coadministered with an ABCB1 inhibitor cyclosporine [22]. However, the use of cyclosporin as a booster for oral administration of taxanes is hampered by its unfavorable immunosuppressive effects, and a new booster is thus needed in place of cyclosporine. Elacridar (GF120918), a third-generation ABCB1(P-gp) inhibitor, has shown promise in this regard. For example, a small clinical study demonstrated that coadministration of elacridar increased bioavailability of oral etoposide by 40%–97% [23]. ABCB1 can also be induced by a number of drugs or chemicals. The lists of representative ABCB1 substrates, inhibitors, and inducers are given in Table 15.2. Notably, some medications commonly used in oncology practice such as morphine, dexamethasone, and rifampicin induce ABCB1 expression [24–26] and could potentially decrease the bioavailability of oral chemotherapeutic agents that are ABCB1 substrates. In addition, some oral chemotherapeutic agents such as small molecule tyrosine kinase inhibitors (TKIs) can modulate ABCB1 function (see Table 15.2). Although there is little clinical evidence showing the influence of ABCB1 inducers on the pharmacokinetics of oral chemotherapeutic agents, one should be cautious when potential ABCB1 inducers are coadministered with the oral chemotherapeutic agents that are ABCB1 substrates.

The human ABCB1 gene is polymorphic. The most common SNPs of *ABCB1* in Caucasians and Asians are C1236T in exon 12, C3435T in exon 26, and G2677T in exon 21, but these SNPs are much less prevalent in African-American populations [27–29]. Interestingly, the frequencies of *ABCB1* SNPs differ between patients with cancer and healthy control populations [30]. Given the important role of ABCB1 in drug absorption and disposition, genetic polymorphisms in the *ABCB1* gene may influence the drug exposure and outcome of chemotherapy. For example, it has been shown that the C3435T and G2677T polymorphisms of *ABCB1* were associated with decreased risk of capecitabine-induced hand-foot syndrome (HFS) [31]. The association of *ABCB1* polymorphisms and the clinical outcome of small molecule TKIs have been reported. A retrospective study in patients with renal cell carcinoma (RCC) treated with sunitinib has demonstrated that the 1236T-3435C-2677G haplotype was associated with improved progression-free survival [32]. The *ABCB1* polymorphisms were also associated with increased trough level of erlotinib [33]; surprisingly, the erlotinib-treated patients carrying *ABCB1* variants showed a shorter progression-free survival compared to those carrying the wild type [34]. Conflicting results on the clinical impact of *ABCB1* polymorphisms may reflect the complex disposition pathway of the substrate drugs. For example, the TKIs (e.g., gefitinib, erlotinib, sunitinib) were found to be the dual substrates for both ABCB1 and ABCG2 transporters and were also

TABLE 15.2 Chemotherapeutic Agents that are Substrates, Representative Inhibitors, and Inducers of ABCB1

Substrates (Chemotherapeutic Agents)	Inhibitors	Inducers
Anthracyclines (daunorubicin, doxorubicin, epirubicin)	Macrolides (Azithromycin, clarithromycin, erythromycin)	Chlorambucil
Capecitabine	Antiarrhythmic (amiodarone, carvedilol, diltiazem, lidocaine, verapamil)	Cisplatin
Dasatinib	Azole antifungal (ketoconazole, itraconazole)	Clotrimazole
Etoposide	Chlorpromazine	Colchicine
Erlotinib	Dasatinib	Daunorubicin
Imatinib	Dipyridamole	Dexamethasone
Melphalan	Doxazosin	Doxorubicin
Mitomycin C	Fenofibrate	Efavirenz
Mitoxantrone	Fentanyl	Erythromycin
Taxanes (paclitaxel, docetaxel)	Flavonoids	Etoposide
Rapamycin	Glyburide	Fluorouracil
Tamoxifen	Gefitinib	Hydroxyurea
Temozolomide	Grapefruit juice, garlic, green tea (catechins), orange juice	Insulin
Topotecan, irinotecan	Haloperidol	Lopinavir
Vinca alkaloids (vinblastine, vincristine, vindesine)	hydrocortisone	Methotrexate
—	Imatinib	Mitoxantrone
—	Imipramine	Morphine
—	Lapatinib	Nelfinavir
—	Levothyroxine	Nevirapine
—	Loperamide	Nifedipine
—	Lopinavir	Paclitaxel
—	Loratadine	Phenobarbital
—	Methadone	Phenothiazines
—	Midazolam	Phenytoin
—	Mitomycin C	Prazosin
—	Nelfinavir	Ritonavir
—	Nilotinib	St. John's Wort
—	Proton-pump inhibitors (PPI) (lansoprazole, omeprazole, pantoprazole)	Tacrolimus
—	Phenothiazines	Tamoxifen
—	Progesterone	—
—	Promethazine	—
—	Propafenone	Trazodone

(continued overleaf)

TABLE 15.2 (continued)

Substrates (Chemotherapeutic Agents)	Inhibitors	Inducers
—	Ritonavir	Verapamil
—	SSRIs (paroxetine, sertraline, fluoxetine)	Vinblastine
—	Sorafenib	Vincristine
—	Sunitinib	Yohimbine
—	Statins (atorvastatin, simvastatin, lovastatin)	—
—	Spironolactone	—
—	Tacrolimus	—
—	Tamoxifen	—

Data are obtained from <http://www.genemedrx.com/PGPtable.php>.

metabolized by CYP3A4. This means that potential ABCB1 effect could be marked by the activity of ABCG2 or CYP3A4. Hence, a systemic analysis of polymorphisms in multiple genes known or suspected to contribute to drug disposition and response would provide better insights on the genetic impact of oral chemotherapy.

15.3.3 Other Factors

15.3.3.1 Antacid Medications. Most chemotherapeutic agents are weak acids or weak bases. They exist in solution at equilibrium between unionized and ionized forms. It is believed that only unionized species are sufficiently lipophilic to penetrate membranes. The fraction unionized is determined by both the pK_a of the drug and the pH in the GI tract. Based on the prediction of the pH partition hypothesis, weak bases are absorbed faster (because of predominant fraction unionized) in less acidic environment (e.g., pH 8.0) than in acidic condition (e.g., pH 1.0), and the converse holds for weak acids. The pH in GI tract varies between 1.5 and 7.5. Certain drugs (e.g., H_2 blockers and proton pump inhibitors) could alter the pH of GI fluid and thereby potentially influencing the oral absorption and pharmacokinetics of oral chemotherapeutic agents such as dasatinib or nilotinib [35,36]. It is noted that the pH change caused by H_2 blockers or proton pump inhibitors lasts for hours, and therefore, drug interaction may still occur even with separate administration of oral chemotherapeutic agents from acid suppressants. For instance, the solubility and bioavailability of dasatinib are pH dependent, diminishing at low pH values. It has been shown that dasatinib exposure was reduced by 60% even when it was administered 10 h after the administration of famotidine, a histamine H_2 receptor antagonist that inhibits stomach acid production [37]. As drug–drug interaction studies for many of the combinations of chemotherapeutic and antacid agents may not be available, the combination of oral chemotherapeutic agents with antacid medications should be used with caution and be avoided if possible.

15.3.3.2 Food Effect. It has been demonstrated that food affects the GI physiology (e.g., gastric emptying, intestinal motility, acid secretion, bile secretion, enzyme secretion, and blood flow); these changes may influence drug absorption, particularly

TABLE 15.3 Influence of Food on the Bioavailability of Selected Oral Chemotherapeutic Agents

Drug [Ref.]	Effect From Food	Recommended Administration
Melphalan [40]	39% reduction of AUC and 27% reduction of bioavailability	Fasting
Lapatinib [39]	167% increase of AUC by low fat meal and 325% increase of AUC by high fat meal	Fasting
Capecitabine [44]	51% increase of capecitabine AUC by fasting but only 13% increase of 5-FU AUC by fasting	With food
Nilotinib	50% increase of AUC by high fat diet	Fasting
Dasatinib [46]	14% increase in AUC by high fat meal	With or without
Pazopanib	~Twofold increase in AUC and $C_{\max}$ with a high fat or low fat meal.	1 h before or 2 h after a meal
Everolimus [47]	Delayed $T_{\max}$ by 1.75 h, reduced $C_{\max}$ by 53%, and reduced AUC by 21%	With or without
Vorinostat [48]	38% increase in AUC_{0-8} but decreased absorption rate (2.5-h delay in $T_{\max}$). Overall, no significant effect.	With food

AUC, area under the concentration–time curve; $C_{\max}$, maximum serum concentration.

for poorly water-soluble drugs [38]. The delayed gastric emptying in the presence of food would result in delayed drug absorption, but the longer gastric residence time would allow more time for dispersion and dissolution of poorly water-soluble drugs. The secretion of bile salts and the larger volume of GI fluid after a meal may also increase the dissolution rate of hydrophobic drugs, thereby increasing the extent of absorption [38]. It has been reported that the bioavailability of some oral chemotherapeutic agents is influenced by concurrent food intake. Table 15.3 presents the examples of food effects on the bioavailability of selected chemotherapeutic agents. For example, the systemic exposure [i.e., area under the plasma concentration–time curve (AUC)] of lapatinib is increased by 2.67-fold and 4.25-fold with a low fat and high fat meal, respectively, compared to the fasting state [39]. As interindividual absorption variability increases significantly with food intake and is unpredictable, lapatinib is recommended in a fasting state. The AUC of melphalan was reduced by 40% when the drug was administered with food [40]. The pharmacokinetics of gefitinib, sunitinib, sorafenib, and imatinib are not significantly affected by concomitant food consumption [41–43]. Given potential food effect on the oral absorption and pharmacokinetics, patients should be instructed to take oral chemotherapeutic agents with or without meal. For example, the combination of capecitabine and lapatinib is approved for the second-line human epidermal growth factor 2 (HER2) positive advanced breast cancer. Patients on this combination should take lapatinib on an empty stomach daily and capecitabine with meals twice a day. Another example is the use of dasatinib or nilotinib as the second-line treatment for patients with chronic myeloid leukemia (CML) after imatinib failure. Dasatinib is commonly prescribed once daily and can be taken with or without food, whereas nilotinib is taken twice daily and should be taken on an empty stomach because its absorption is increased when taken with food and could cause serious toxicities (e.g., QT prolongation).

15.3.3.3 Surgery. Several surgical procedures (e.g., gastrectomy, bariatric surgery, and the Whipple procedure) could potentially affect the absorption and pharmacokinetics of oral chemotherapeutic agents. For example, it has been shown that prior gastrectomy significantly reduces the bioavailability of nilotinib, thereby causing decreased efficacy [30]. Capecitabine is an oral agent frequently used in GI malignancy, and the influence of gastrectomy on capecitabine pharmacokinetics is currently being evaluated in an ongoing clinical trial. Data reported on the effect of gastrectomy on drug absorption are in some instances contradictory. For example, an oral fluoropyrimidine TS-1 (Taiho Pharmaceutical) is an orally active combination of tegafur (a prodrug of fluorouracil), gimeracil (an inhibitor of dihydropyrimidine dehydrogenase, thereby inhibiting degradation of fluorouracil), and oteracil (which inhibits the phosphorylation of fluorouracil in the gastrointestinal tract thereby reducing gastrointestinal toxicity of fluorouracil) in a molar ratio of 1:0.4:1 while one study showed the pharmacokinetics of an oral fluoropyrimidine TS-1 was not altered by gastrectomy, another study indicated an increased absorption of TS-1 after gastrectomy [49,50].

15.4 MAJOR CLASSES OF ORAL CHEMOTHERAPEUTIC AGENTS

Broadly, oral chemotherapeutic agents can be classified as traditional cytotoxic agents (e.g., alkylating agents, antimetabolites, and plant alkyloids), novel molecularly targeted agents (e.g., small molecule TKIs, mTOR inhibitors, and HDAC inhibitors), hormonal agents (e.g., tamoxifen, letrozole, and anastrozole), and immune-modulating agents (e.g., thalidomide and lenalidomide). Table 15.4 summarizes the mechanisms of action and clinical pharmacology of the major classes of oral chemotherapeutic agents that are currently available for the treatment of cancers.

15.4.1 Traditional Oral Cytotoxic Agents

Traditional oral cytotoxic agents can be grouped into alkylating agents, antimetabolites, and plant alkyloids, based on their classification and phase of the cell cycle that they act on. Alkylating agents are cell cycle nonspecific. They cause cell death by forming DNA or RNA cross-links via a process known as alkylation (i.e., substituting an alkyl group for a hydrogen atom). Antimetabolites act on the S phase of cell cycle. They interfere with nucleic acid synthesis by substituting themselves for purines or pyrimidines or by inhibiting critical enzymes involved in nucleic acid synthesis. The plant alkyloids target the G2 phase of cell cycle. They inhibit topoisomerase II, thus preventing cells from entering the M phase of cell cycle.

15.4.1.1 Alkylating Agents. Alkylating agents have been available for several decades. The oral drugs in this class include busulfan, melphalan, cyclophosphamide, chlorambucil, estramustine, altretamine, procarbazine, and temozolomide [51–54]. Among them, busulfan, melphalan, and cyclophosphamide are available as formulations for both intravenous and oral administration. The mechanism of action and pharmacokinetic characteristics of busulfan, chlorambucil, cyclophosphamide, melphalan, and temozolomide are summarized in Table 15.4. Of note, cyclophosphamide and temozolomide are prodrugs that require metabolic activation to exert their pharmacological activities.

TABLE 15.4 Mechanisms of Action and Clinical Pharmacology of Major Classes of Oral Chemotherapeutic Agents^a

Drug	Mechanisms of Action	F (%)	T _{max} (h)	T _{1/2} (h)	Metabolism	Major Circulating Metabolites	Elimination	Plasma Protein Binding
Alkylating agents								
Chlorambucil	A bifunctional alkylating agent of the nitrogen mustard type cross-linking tumor cell DNA	100	1	1.5	Rapidly metabolized to active metabolites	Phenylacetic acid mustard (active)	<1% of the dose excreted in urine as unchanged drug	~99%
Cyclophosphamide	A prodrug that is biotransformed to active alkylating metabolites cross-linking tumor cell DNA	>75	N/A	3–12	Metabolized by a mixed function microsomal oxidase system in the liver to form active alkylating metabolites	4-Hydroxy cyclophosphamide (active)	5–25% of the dose excreted in urine as unchanged drug	Weakly bound
Melphalan	An alkylating agent of the bischloroethylamine type cross-linking DNA and RNA and inhibiting protein synthesis	100	1	1.5	Eliminated from plasma primarily by chemical hydrolysis to monohydroxymelphalan and dihydroxymelphalan	Monohydroxymelphalan	Low	60–90%, mostly to HSA and AAG

(continued overleaf)

TABLE 15.4 (continued)

Drug	Mechanisms of Action	F (%)	T _{max} (h)	T _{1/2} (h)	Metabolism	Major Circulating Metabolites	Elimination	Plasma Protein Binding
Temozolomide	A prodrug that undergoes rapid nonenzymatic conversion to the DNA alkylating compound MTIC	~100	~1	1.8	Spontaneously hydrolyzed at physiologic pH to the reactive species MTIC and to temozolomide acid metabolite	MTIC (active)	5.6% of the dose excreted in urine as unchanged drug	Weakly bound (~15%)
Antimetabolites								
Methotrexate	An antimetabolite that inhibits dihydrofolic acid reductase, thereby interfering with DNA synthesis, repair, and cellular replication	~60	1–2	3–15	Undergoes hepatic and intracellular metabolism to active polyglutamated forms, and a small amount of metabolism to 7-hydroxy-methotrexate	Polyglutamated metabolites (active); 7-hydroxy-methotrexate (inactive)	Renal excretion by glomerular filtration and active tubular secretion	50%
Fludarabine phosphate (2F-ara-AMP)	A synthetic purine nucleotide antimetabolite agent that is dephosphorylated in plasma to form the active metabolite (2F-ara-A), functioning as a DNA chain terminator	50–65	1–2	3	Rapidly dephosphorylated in plasma to active 2F-ara-A, which then enters into the cell	2F-ara-A (active)	Renal clearance of 2F-ara-A represents ~40% of the total body clearance of fludarabine phosphate	19–29%

Capecitabine	A prodrug that is metabolized to 5-FU, which is further converted to the active FdUMP and FUTP, thus interfering with DNA, RNA, and protein synthesis	55	0.75	1.5	Capecitabine is hydrolyzed by carboxyesterase in the liver to 5'-deoxy-5-fluorocytidine (5'-DFCR) that is subsequently converted by cytidine deaminase in most tissues (including tumors) to 5'-deoxy-5-fluorouridine (5'-DFUR) which is then hydrolyzed by thymidine phosphorylase to the active drug 5-FU	5-FU	95.5 and 2.6% of administered radioactivity recovered in urine and feces, respectively.	60%, mainly to HSA
Plant alkyls Etoposide	A topoisomerase II inhibitor that acts at the premitotic stage of cell division, inhibiting DNA synthesis	50	1	4–11	Metabolized mainly by hepatic CYP3A4, and to a lesser extent by CYP1A2	<i>O</i> -desmethyl etoposide (inactive); hydroxy acid [4'-demethylepipodophyllic acid-9-(4,6- <i>O</i> -(<i>R</i>)-ethylidene- β - <i>D</i> -glucopyranoside)] (inactive)	44–60%, up to 16%, and <6% of administered radioactivity recovered in urine, feces, and bile, respectively	97%, mainly to HSA

(continued overleaf)

TABLE 15.4 (continued)

Drug	Mechanisms of Action	F (%)	T _{max} (h)	T _{1/2} (h)	Metabolism	Major Circulating Metabolites	Elimination	Plasma Protein Binding
Tyrosine kinase inhibitors								
Imatinib	A TKI of Bcr-Abl, PDGF, and SCF, and c-Kit	98	2–4	15–18	Metabolized predominantly by hepatic CYP3A4, and to a lesser extent by CYP1A2, CYP2D6, CYP2C9, and CYP2C19	<i>N</i> -desmethyl imatinib (active)	5% of the dose excreted in urine as unchanged drug	95%, mostly to HSA and AAG
Dasatinib	A dual BCR-ABL/SRC family TKI; binding to active and inactive conformations of BCR-ABL, thereby overcoming the most common mechanisms of resistance to imatinib	~100	0.5–6	3.6–5.4	Metabolized in the liver by CYP3A4, flavin-containing mono-oxygenase-3, and UGTs	<i>O</i> -oxide desatinib (active)	<1 and 19% of the dose excreted in urine and feces, respectively, as unchanged drug	96%
Gefitinib	EGFR TKI	60	3–7	48	Metabolized predominantly by hepatic CYP3A4 and CYP3A5, and to a lesser extent by CYP2D6	<i>O</i> -desmethyl gefitinib (active)	<4% of the dose excreted in urine as unchanged drug	97%, mostly to HSA and AAG

Erlotinib	EGFR TKI	60	4	36	Metabolized predominantly by CYP3A4/5, and to a lesser extent by CYP1A2 and CYP1A1	OSI-420, OSI-413	<9% of the dose excreted in urine as unchanged drug	93%, mostly to HSA and AAG
Sorafenib	A multikinase inhibitor, inhibiting C-Raf, B-Raf (wild-type and mutant), ERK, VEGFR (types 1, 2, and 3), PDGFR- β , Flt-3, c-KIT, and p38 α , a member of the MAP kinase family	38-49	2-6	25-48	Metabolized by hepatic CYP3A4 and UGT1A9	<i>N</i> -oxide sorafenib (active)	77% and 19% of administered radioactivity recovered in feces and urine, respectively	99.5%
Sunitinib	A broad-spectrum receptor TKI, specifically inhibiting VEGFR (types 1, 2, and 3), PDGFR α and PDGFR- β , c-KIT, Flt-3, colony-stimulating factor receptor type 1, and the glial cell-line-derived neurotrophic factor receptor	59	6-12	40-60	Metabolized predominantly by hepatic CYP3A4	SU012662 (active)	61 and 16% of administered radioactivity recovered in feces and urine, respectively	95%

(continued overleaf)

TABLE 15.4 (continued)

Drug	Mechanisms of Action	F (%)	T _{max} (h)	T _{1/2} (h)	Metabolism	Major Circulating Metabolites	Elimination	Plasma Protein Binding
Pazopanib	multi-tyrosine kinase inhibitor of VEGFR-1, 2, and 3, PDGFR- α and - β , FGFR -1 and 3, cytokine receptor (Kit), interleukin-2-receptor-inducible T-cell kinase (Itk), leukocyte-specific protein tyrosine kinase (Lck), and transmembrane glycoprotein receptor tyrosine kinase (c-Fms)	—	2–4	31	Metabolized mainly by CYP3A4, with minor contribution from CYP1A2 and CYP2C8	—	Primarily via feces with renal elimination accounting for <4% of the administered dose	99%
Lapatinib	Inhibiting EGFR and HER2	N/A	3–4	14–24	Metabolized predominantly by hepatic CYP3A4 and CYP3A5, and to a lesser extent by CYP2C19 and CYP2C8	O-dealkylated lapatinib (reactive) and N-dealkylated lapatinib (reactive)	27 and <2% excreted in feces and in urine, respectively, as unchanged drug	99%, mostly to HSA and AAG
mTOR inhibitors								
Everolimus	A derivative of rapamycin, inhibiting mTOR	N/A	1–2	30	Metabolized by CYP3A4	Hydroxyl- and desmethyl-metabolites (inactive)	80% of administered radioactivity recovered in feces as metabolites	74%

Histone deacetylase inhibitors									
Vorinostat	Inhibiting the enzymatic activity of histone deacetylases HDAC1, HDAC2, and HDAC3 (Class I) and HDAC6 (Class II), thus causing the accumulation of acetylated histones and inducing cell cycle arrest and/or apoptosis of some transformed cells	43	2–10	1.3–2	The major pathways of vorinostat metabolism involve glucuronidation and hydrolysis followed by β -oxidation	<i>O</i> -glucuronide of vorinostat (inactive) and 4-anilino-4-oxobutanoic acid (inactive)	<1% of the dose excreted in urine as unchanged drug	71%	
Hormonal agents									
Tamoxifen	A nonsteroidal agent with antiestrogenic effects through competitive binding to estrogen receptor	N/A	5	120-168	Extensively metabolized by CYP3A4, CYP3A5, CYP2D6, and CYP2C9	Endoxifen (active)	65% of administered radioactivity recovered in feces	Moderate bound	
Letrozole	A nonsteroidal competitive inhibitor of aromatase, thus inhibiting the conversion of androgens to estrogens	100	1–2	48	Metabolized by CYP3A4 and CYP2A6 to inactive metabolites whose glucuronide conjugate is excreted renally.	Inactive metabolites	90% of administered radioactivity recovered in urine, among which 75% and 6% as glucuronide metabolite and unchanged drug respectively.	Weakly protein bound	

(continued overleaf)

TABLE 15.4 (*continued*)

Drug	Mechanisms of Action	F (%)	T _{max} (h)	T _{1/2} (h)	Metabolism	Major Circulating Metabolites	Elimination	Plasma Protein Binding
Anastrozole	A potent and selective nonsteroidal aromatase inhibitor, significantly lowering serum estradiol concentrations and has nodetectable effect on formation of adrenal corticosteroids or aldosterone	—	—	50	Metabolized by <i>N</i> -dealkylation, hydroxylation, and glucuronidation. Three metabolites of anastrozole have been identified in human plasma and urine. The known metabolites are triazole, a glucuronide conjugate of hydroxyanastrozole, and a glucuron	Two major inactive metabolites: triazole (a glucuronide conjugate of hydroxyanastrozole) and a glucuronide conjugate of anastrozole	Eliminated primarily via hepatic metabolism (~85%) and to a lesser extent, renal excretion (~11%)	40%
Exemestine	An irreversible, steroidal aromatase inactivator that binds irreversibly to the active site of aromatase causing its inactivation	42	1.2–2.9	24	Metabolized by CYP3A4 and aldoketoreductases	17-Hydroxy-exemestane	<1% of the dose excreted in urine as unchanged drug	90%, mostly to HSA and AAG

Immune-modulating agents								
Thalidomide	Possessing immunomodulatory, antiinflammatory, and antiangiogenic properties	N/A	2.9–5.7	5–7	Undergo nonenzymatic hydrolysis in plasma to multiple products	N/A	<0.7% of the dose excreted in urine as unchanged drug	55 and 66%, respectively, for (+)-(<i>R</i>)- and (–)-(<i>S</i>)-thalidomide
Lenalidomide	Possessing immunomodulatory, antiangiogenetic, antineoplastic properties	50	0.5–4	3	Unknown	N/A	67% of the dose excreted in urine as unchanged drug	30%

AAG, alpha-1 acid glycoprotein; CYP, cytochrome P450; F, oral bioavailability; HSA, human serum albumin; TKI, tyrosine kinase inhibitor; $T_{\max}$, time to reach maximum plasma concentration; $T_{1/2}$, elimination half-life; UGT, UDP-glucuronosyltransferase; MTIC, 3-methyl-(triazene-1-yl)imidazole-4-carboxamide; 5-FU, 5-fluorouracil; FdUMP, 5-fluoro-2-deoxyuridinemonophosphate; FUTP, 5-fluorouridine triphosphate; PDGF, platelet-derived growth factor; SCF, stem cell factor; Flt-3, Fms-like tyrosine kinase-3; FGFR, fibroblast growth factor receptor; Bcr-Abl, breakpoint cluster region-Abelson; c-KIT, stem cell growth factor receptor; PDGFR, platelet-derived growth factor receptor; EGFR, epidermal growth factor receptor.

N/A, data not available.

^aData are obtained from the drug package inserts.

Oral busulfan is a relatively inexpensive and well-tolerated drug at low doses. It is widely used for benign as well as malignant hematological diseases. High dose busulfan is often incorporated into hematopoietic stem cell transplant preparative regimens, but the bioavailability of high dose oral busulfan varies widely from 10% to 100% [55]. Variable bioavailability can cause substantial variability of system exposure to busulfan. Increased systemic exposure may result in a higher incidence of toxicity such as veno-occlusive disease (VOD) [56,57], whereas inadequate drug exposure may lead to graft failure [58,59]. Owing to the large interindividual pharmacokinetic variability of busulfan at high doses, many transplant centers only use intravenous busulfan for transplant conditioning. However, the intravenous formulation of busulfan is not available in many countries and is more expensive than oral formulation. Oral melphalan is currently used for patients with multiple myeloma who are not transplant candidates [60]. Use of melphalan should be avoided for potential transplant candidates as exposure to alkylating agents can make stem cell collection difficult and delay marrow recovery post transplant [61,62]. Similar to busulphan, high dose oral melphalan is associated with variable drug absorption and substantial pharmacokinetic variability. Intravenous melphalan, however, is safer and has a much more predictive outcome than oral melphalan for transplant conditioning [63,64].

Cyclophosphamide can be administered intravenously or orally. It is well absorbed after oral administration with a bioavailability of >75%. Notably, cyclophosphamide exhibits 3.5 times more alkylating potency when given orally than when given intravenously [65]. Cyclophosphamide is a prodrug that requires biotransformation to active alkylating metabolites, principally by a mixed function microsomal oxidase system in the liver. There are multiple active metabolites of cyclophosphamide, including 4-hydroxy-cyclophosphamide, alcophosphamide, 4-keto-cyclophosphamide, phosphoramidate mustard, and acrolein. Acrolein is a known causative metabolite of hemorrhagic cystitis, a condition occurring more commonly when cyclophosphamide is administered intravenously than orally [66,67]. Recently, metronomic use (frequent administration of low dose) of oral cyclophosphamide has been increasingly used for the treatment of metastatic breast cancer, especially for elderly and/ or borderline poor performance status patients, given its favorable toxicity profile and comparable efficacy compared to conventional every 3-week administration [68,69].

Temozolomide is also a prodrug that undergoes rapid nonenzymatic conversion to the DNA-alkalating metabolite, 5-(3-methyltriazen-1-yl)imidazole-4-carboxamide (MTIC). It is almost completely absorbed after oral administration. Temozolomide is approved by the FDA for the treatment of central nervous system (CNS) malignancies including glioblastoma multiforme and other solid tumors [70]. Many alkylating agents can penetrate cerebrospinal fluid (CSF) with various CSF penetration rates (AUC_{CSF}/AUC_{plasma}) [71]. The CSF penetration rate of temozolomide is 20%, giving it some advantage for sensitive CNS malignancies [72].

It is interesting to note that both intravenous and oral formulations of ifosfamide were investigated, but only intravenous administration is approved by the US FDA. Like cyclophosphamide, ifosfamide is also a prodrug that requires bioactivation in the liver. When given orally, ifosfamide caused increased neurological toxicity, probably because of high plasma levels of its toxic metabolite chloroacetaldehyde that is formed from first-pass metabolism [73]. A randomized phase II study comparing intravenous and oral administration of ifosfamide in patients with non-small-cell lung cancer (NSCLC) was prematurely terminated because of excessive neurotoxicity in the

oral administration cohort [74]. This example of enhanced toxicity with oral ifosfamide alerted the oncology community that first-pass metabolism may play a critical role in the toxicity profile of oral chemotherapeutic agents.

15.4.1.2 Antimetabolites. Antimetabolites exert antitumor activity by interfering with nucleic acid synthesis or nucleotide synthesis. The oral drugs in this class include fludarabine, methotrexate, and capecitabine. Fludarabine is a purine antagonist. Intravenous fludarabine is used to treat select hematological malignancies. It is an important component of chemotherapeutic regimens for the treatment of chronic lymphoid leukemia (CLL) [75,76]. Oral fludarabine has demonstrated comparable clinical efficacy to intravenous fludarabine and has been recently approved by the FDA for treatment of CLL [77,78].

Capecitabine is an oral fluoropyrimidine and a prodrug of 5-fluorouracil (5-FU). It is widely used for the treatment of a variety of solid tumors including colorectal, breast, and gastric cancers. Capecitabine is hydrolyzed by carboxylesterase in the liver to form 5'-deoxy-5-fluorocytidine (5'-DFCR) that is subsequently converted by cytidine deaminase in tissues (including tumor cells) to 5'-deoxy-5-fluorouridine (5'-DFUR), which is then hydrolyzed by thymidine phosphorylase to 5-FU. 5-FU is further converted to the active 5-fluoro-2-deoxyuridine monophosphate (FdUMP) and 5-fluorouridine triphosphate (FUTP), thus interfering with DNA, RNA, and protein synthesis. Three enzymes, carboxylesterase, cytidine deaminase, and thymidine phosphorylase, play important roles in the bioactivation of capecitabine. As tumor cells express higher thymidine phosphorylase, capecitabine works more specifically on tumor cells than normal tissues [79–81]. Multiple clinical studies and a large meta-analysis support that capecitabine as a single agent or in combination with other chemotherapies demonstrates equivalent clinical benefit as intravenous 5-FU for the treatment of metastatic colorectal and gastric cancers [82–87]. The toxicity profile of capecitabine is, overall, comparable to continuous intravenous infusion of 5-FU [87].

Uracil-ftorafur (UFT) is an oral fluoropyrimidine-based formulation consisting of two components: tegafur, a prodrug of 5-FU, and uracil, a dihydropyrimidine dehydrogenase (DPD) inhibitor. DPD is an important enzyme in metabolism/detoxification of 5-FU. The vast majority (~80–85%) of administered 5-FU is metabolized by DPD in the liver into the inactive form, dihydrofluorouracil (FDHU) and excreted as a fluoro- β -alanine. DPD expression has been related to tolerance and response to 5-FU-based chemotherapy. Specifically, low expression or absence of DPD has been associated with greater accumulation of 5-FU and thereby, increased risk of severe toxicities, while high expression of DPD has been associated with poor response to 5-FU [88,89]. Patients lacking the DPD enzyme may experience severe to lethal toxicities when receiving 5-FU-based chemotherapy. Genetic aberration in the dihydropyrimidine dehydrogenase (*DPYD*) gene, such as exon skipping, deletion, and missense mutation, contributes to a DPD deficiency phenotype. The prevalence of DPD deficiency varies among different races, highest in African-Americans (8%), modest in Caucasians (2.8%), and lowest in Asians (<1%) [90–92]. The most known *DPYD* SNPs associated with grade 3 and 4 toxicities are IVS14 + 1G > A, 2846A > T, 1679T > G and 85T > C [93]. In particular, the exon-14-skipping mutation IVS14 + 1G > A, a G-to-A point mutation within the 5'-splicing site of intron 14, leads to a mutant DPD that lacks amino acids 581–635 and consequently lacks catalytic activity. The allele frequency of this mutation was 0.91% in a Dutch Caucasian population [94]. In

patients heterozygous for the IVS14 + 1G > A allele, half of the mean normal activity of DPD is found, which is sufficient to lead to severe 5-FU toxicities. In patients homozygous for the IVS14 + 1G > A allele, DPD activity is completely lacking and 5-FU toxicities become life-threatening and sometimes fatal [95,96]. The idea of combination of a DPD inhibitor with 5-FU is to make everyone DPD deficient regardless of the DPD genotype, and thus no genotyping-guided dose adjustment is needed.

Similar to UFT, TS-1 is an oral fluoropyrimidine-based formulation consisting of three components: tegafur (a 5-FU prodrug), 5-chloro-2,4-dihydroxypyridine (a DPD inhibitor), and potassium oxonate (an inhibitor of orotate phosphoribosyltransferase). Potassium oxonate inhibits 5-FU phosphorylation, which is believed to be the cause of the GI toxicities associated with 5-FU [97]. There is a paucity of data directly comparing the efficacy and toxicity among these three oral fluoropyrimidines. One phase II trial conducted in South Korea showed similar efficacy and side effects between capecitabine and S-1 in elderly Korean patients [98]. At present, only capecitabine is available in the United States.

15.4.1.3 Plant Alkylolds. *pt*Etoposide (VP-16) is a semisynthetic derivative of podophyllotoxin whose first topical use for antineoplastic purposes was reported in the nineteenth century [99]. Etoposide can cause single-strand DNA breaks and cell death in G2 phase via topoisomerase II inhibition. Both intravenous and oral etoposide are available and are used widely for a variety of solid and hematological malignancies. Oral absorption of etoposide exhibits dose-dependency, with lower bioavailability at higher doses [100,101]. To overcome this problem, the prodrug of etoposide, etoposide phosphate, was investigated. However, the pharmacokinetics of etoposide phosphate was found to be similar to that of etoposide [102]. In clinical practice, the oral etoposide is rarely used as it is only approved for small cell lung cancer and it is largely used for palliative purpose with occasional use in curative intent [103,104]. The recommended oral dose is twice of the intravenous dose.

15.4.2 Novel Molecularly Targeted Oral Agents

15.4.2.1 Small Molecule Tyrosine Kinase Inhibitors (TKIs). Small molecule TKIs directly inhibit the enzymatic activity of the target protein kinase by interfering with the ATP-binding site of the tyrosine kinase (TK), thereby preventing autophosphorylation of the kinase and subsequently blocking the downstream cellular signaling pathways that play an important role in tumor growth and progression. Table 15.5 lists the FDA-approved small molecule TKIs and their main targets. The use of small molecule TKIs has significantly changed the outcomes for some cancers. For example, imatinib has had a dramatic effect on CML, and sunitinib has revolutionized the treatment of renal cell carcinoma (RCC). Meanwhile, these agents have expanded the concept of individually tailored cancer treatment because they are likely to be effective in subsets of patients whose tumors have specific molecular traits. For instance, specific mutations in the epidermal growth factor receptor (EGFR) TK domain in non-small cell lung cancer (NSCLC) are important determinants of dramatic response to the EGFR inhibitors gefitinib and erlotinib. Kinase mutations also play a role in the intrinsic or acquired resistance to TKI therapy. One example is from imatinib whereby point mutations in breakpoint cluster region-abelson (BCR-ABL) render the ABL kinase

TABLE 15.5 Small Molecule Tyrosine Kinase Inhibitors Approved by the US FDA for Cancer Treatment

Drug	Main Target	FDA-Approved Indications
Imatinib (Gleevec)	BCR-ABL, c-KIT, PDGFR	Acute lymphocytic leukemia, chronic myeloid leukemia, gastrointestinal stromal tumor
Gefitinib (Iressa)	EGFR	Non-small-cell lung cancer
Erlotinib (Tarceva)	EGFR	Non-small-cell lung cancer, pancreatic cancer
Lapatinib (Tykerb)	HER2/neu, EGFR	Breast cancer with HER2/neu overexpression
Dasatinib (Sprycel)	BCR-ABL, SRC family, c-KIT, PDGFR	Chronic myeloid leukemia, acute lymphocytic leukemia
Sorafenib (Nexavar)	B-RAF, VEGFR, EGFR, PDGFR	Renal cell carcinoma, hepatocellular carcinoma
Sunitinib (Sutent)	VEGFR, PDGFR, c-KIT, FLT-3	Renal cell carcinoma, gastrointestinal stromal tumor
Pazopanib (Votrient)	VEGFR, PDGFR, c-KIT	Renal cell carcinoma

BCR-ABL, breakpoint cluster region-Abelson; c-KIT, stem cell growth factor receptor; PDGFR, platelet-derived growth factor receptor; EGFR, epidermal growth factor receptor; VEGFR, vascular endothelial growth factor receptor; FLT-3, Fms-like TK.

resistant to imatinib, which is associated with relapse in patients with advanced CML receiving imatinib.

Imatinib (STI 571, Gleevec®) is the first-approved small molecule TKI. It targets the Philadelphia-chromosome-associated BCR/ABL fusion TK, a genetic causal mechanism of CML. Imatinib also inhibits platelet-derived growth factor receptor (PDGFR) and c-kit, a proto-oncogene linked to gastrointestinal stromal tumors (GISTs). Imatinib is FDA approved for the treatment of CML and GISTs [105,106]. In a phase III trial, 75 patients with CML receiving imatinib achieved a major cytogenetic response, which was durable with an 85% overall survival at eight years [107–109]. Primary resistance to imatinib occurs in 10–15% of patients. Primary resistance could be due to inadequate intracellular drug concentration. Several mechanisms are implicated in the decrease of effective intracellular concentration of imatinib, among which the most important includes the increased protein binding to alpha-1 acid glycoprotein [110,111], increased drug efflux due to overexpression of ABC transporters such as ABCB1 and ABCG2 [112,113], or reduced cellular uptake of imatinib due to dysregulation of uptake transporters such as the organic cation transporter (OCT1) [114,115]. Acquired (secondary) resistance after initial response to imatinib is observed in 8–10% of patients. The most common molecular mechanism of acquired resistance to imatinib is point mutations at the kinase domain that change the conformation of the c-ABL kinase, thus reducing imatinib-binding affinity to the kinase. More than 50 different point mutations in *ABL* have been identified to be associated with imatinib resistance [116]. For example, the T315I mutation was identified in 15% of patients with CML developing resistance to imatinib [117]. The drug-resistant BCR-ABL point mutation can be found in imatinib-naïve or imatinib-treated patients with CML. To target imatinib-resistant mutant forms of BCR-ABL, second generation of ABL kinase inhibitors such as nilotinib and dasatinib have been developed. Nilotinib was specifically designed

to target mutant forms of BCL-ABL, showing ~30-fold more potency than imatinib for inhibition of mutant BCL-ABL [116]. Dasatinib is a potent inhibitor of BCL-ABL, Src-family kinases, KIT, and PDGFR. On the basis of promising data from phase I and II trials, dasatinib has been recently approved for the treatment of patients with imatinib-resistant CML or Philadelphia chromosome-positive acute lymphoblastic leukemia (ALL). About 50% of patients with acquired resistance to imatinib achieve major cytogenetic response to dasatinib and nilotinib [118,119].

Gefitinib and erlotinib are orally bioavailable, small molecule EGFR-TK inhibitors that target the ATP cleft within the EGFR-TK to prevent autophosphorylation of the receptor, and thus inhibit tumor growth and metastasis. Treatment with gefitinib or erlotinib results in dramatic clinical response in ~10–30% patients with NSCLC depending on ethnic origin, sex, and smoking history [120–122]. It is clear that specific types of somatic mutations of the EGFR gene confer sensitivity or resistance to EGFR TKI [123,124]. The somatic activating EGFR mutations present in the first four exons (18 through 21) of the TK domain [125–127]. The most common activating mutations include in-frame deletions in exon 19 (e.g., deletion of amino acid residues leucine 747 to glutamic acid 749), single nucleotide mutation (e.g., L858R in exon 21 and G719 in exon 18), and in-frame duplications and/or insertions in exon 20. Overall, the frequency of EGFR-TK-activating mutations is 5–20%, occurring more common in East Asians, women, never smokers, and patients with adenocarcinoma [128]. This mirrors the clinically defined subsets of patients who were most likely to respond to EGFR-TK inhibitors. Like other TKIs, acquired resistance occurs in virtually all NSCLC tumors that initially respond to EGFR-TK inhibitors. The emergence of acquired resistance is conferred by a second point mutation in the TK domain. The most noteworthy clinically relevant mutations associated with resistance to EGFR-TK inhibitors include T790M in exon 20, and D761Y, a T790M-like secondary mutation, in exon 19 [129,130].

Sorafenib, sunitinib, and pazopanib are orally active, small molecule multitargeted TKIs with effects on tumor cell proliferation and tumor angiogenesis. Sorafenib was initially developed as a Raf kinase inhibitor. It was subsequently found to inhibit a variety of kinase receptors, including vascular endothelial growth factor receptors (VEGFR)-1, -2, and -3; PDGFR- β ; FMS-like tyrosine kinase 3 (FLT-3); stem cell factor receptor (KIT); and glial-cell-line-derived neurotrophic (RET) receptor tyrosine kinases. Similarly, sunitinib is a potent inhibitor for VEGFR-1, -2, and -3; c-KIT; PDGFR- α and - β ; FLT-3; colony-stimulating factor receptor type 1 receptor; and RET receptor tyrosine kinase (RET). Pazopanib inhibits vascular epidermal growth factor receptor-1, -2 and -3, PDGFR- α and - β , and c-kit. These agents directly and indirectly regulate tumor growth and angiogenesis. They have been approved for the treatment of advanced RCC, with a response rate of 4% (sorafenib), 25–36% (sunitinib), and 30% (pazopanib). Sorafenib and sunitinib have also been approved for the treatment of hepatocellular carcinoma and GI stromal tumor, respectively. Notably, before their approval, there was no accepted standard treatment for advanced RCC, as previously approved agents [interferon (IFN)- α and interleukin (IL)-2] showed minimal benefit and significant side effects. The multitargeted TKIs have demonstrated clinical benefit and are becoming components of standard of care in patients with metastatic RCC. However, almost all patients develop resistance to treatment eventually, and cure is rarely seen. The majority of patients have transient benefit from therapy before tumors regrow and metastasize (i.e., acquired resistance), and a

small fraction of patients fail to show even initial clinical benefit (i.e., intrinsic resistance). Yet, the exact mechanisms of tumor resistance to these agents are not fully understood.

Lapatinib is a dual TKI that target two members of the human EGFR family, ErbB-1 (EGFR) and ErbB-2 (HER-2) [131]. Although it has EGFR inhibition, its antitumor effect is exclusively observed in HER-2-overexpressing breast cancer [132]. Lapatinib, as a single agent, has modest clinical antitumor activity and can be combined with trastuzumab, cytotoxic agents, and/or endocrine therapy [133–135]. Lapatinib is currently approved only for trastuzumab refractory patients. It is unknown if lapatinib has the same efficacy as trastuzumab in both the metastatic and adjuvant settings. However, ongoing trials will answer this question.

15.4.2.2 mTOR Inhibitors. The mTOR is a serine–threonine kinase and a key protein in the PI3K-AKT pathway. Sirolimus, initially known as rapamycin, forms a complex with its receptor FKBP12 and inhibits the mTOR complex 1 (Mtorc1) [136]. Sirolimus was originally developed as an antifungal drug. It was found to have multiple functional characteristics including antiproliferative, immunosuppressive, and antineoplastic effects. Sirolimus is currently approved by the FDA for use as an immunosuppressant after organ and bone marrow transplant but not as an anticancer agent. Everolimus (oral formulation) and temsirolimus (intravenous formulation) are the analogs of sirolimus. Both demonstrate anticancer activity. Temsirolimus was approved for advanced RCC in poor risk categories in the first-line setting, and everolimus was approved for the second-line treatment for metastatic RCC after failing VEGF inhibitors [137,138].

15.4.2.3 Histone Deacetylase Inhibitors. Vorinostat or suberoylanilide hydroxamic acid (SAHA) is a HDAC inhibitor. Epigenetic modulation of gene expression by histone acetylation was found to play a role in oncogenesis in many cancer types [139]. HDAC inhibitors induce histone acetylation, apoptosis, and cell cycle arrest. In a phase II study in patients with refractory cutaneous T-cell lymphoma, vorinostat demonstrated an overall response rate of 30%, with a median duration of response more than six months. This result led to FDA approval of vorinostat for the treatment of patients with refractory cutaneous T-cell lymphoma [140]. The efficacy of vorinostat has been investigated in multiple other cancers including solid tumors. One randomized placebo-controlled phase II study showed that vorinostat in combination with carboplatin and paclitaxel showed superior response rate when compared with carboplatin, paclitaxel, and placebo [141].

15.4.3 Hormonal Agents

Tamoxifen, a selective estrogen receptor (ER) modulator, is a standard endocrine therapy for the treatment and prevention of ER-positive breast cancer. ER-positive breast cancers are often dependent on estrogen for growth. Selective ER modulators bind to the ligand-binding domain of an ER and block the binding of estrogen. This prevents conformational changes of the ER that is required for its association with coactivators, thus blocking transcriptional activation functions of the ER and subsequently reducing or eliminating estrogen-driven proliferation of ER-positive tumors. Tamoxifen is a prodrug that requires metabolic activation to exert its pharmacological activity. The

metabolism of tamoxifen is involved in hepatic phase I enzymes (including CYP3A4, CYP3A5, CYP2C9, CYP2C19, CYP1A2, CYP2B6, and CYP2D6, as well as flavin-containing mono-oxygenase-1 and -3) and phase II enzymes (such as sulfotransferase 1A1 (SULT1A1)) [142–144]. Specifically, tamoxifen is metabolized by hepatic CYP enzymes (mainly by CYP2D6 and CYP3A4/5) to form two main primary metabolites, 4-hydroxytamoxifen and *N*-desmethyltamoxifen. Both these metabolites are further converted to abundant and pharmacologically active 4-hydroxy-*N*-desmethyltamoxifen (endoxifen). Endoxifen formation from *N*-desmethyltamoxifen is almost exclusively catalyzed by CYP2D6, and formation from 4-hydroxytamoxifen by CYP3A4/5 [143]. In addition, tamoxifen and its metabolites undergo phase II metabolism including sulphation and glucuronidation. Endoxifen and 4-hydroxytamoxifen show much greater affinity for the ER than tamoxifen [143,145]. While 4-hydroxytamoxifen and endoxifen have a similar antiestrogen activity, endoxifen plasma concentrations are 6- to 12-fold higher than those of 4-hydroxytamoxifen [146], suggesting that endoxifen is the predominant and crucial active metabolite responsible for the *in vivo* pharmacological activity of tamoxifen.

Given the key role of CYP2D6 in catalyzing the conversion of tamoxifen to its abundant active metabolite endoxifen, altered CYP2D6 activity due to either genetic or environmental (drug-induced or drug-inhibited) factor could directly affect endoxifen concentrations and likely the clinical outcome of patients treated with tamoxifen. There is evidence that women with nonfunctional and reduced-function *CYP2D6* alleles appear to have significantly lower circulating endoxifen concentrations than those with wild-type *CYP2D6* [147,148]. Similarly, concomitant CYP2D6 inhibitors, such as certain selective serotonin reuptake inhibitors (SSRIs) (fluoxetine and paroxetine) or selective noradrenaline reuptake inhibitors (SNRIs), have been shown to reduce the plasma concentrations of endoxifen [147,149]. It has also been shown that the use of CYP2D6 inhibitors such as SSRIs and SNRIs has a negative impact on the efficacy of tamoxifen [147]. Collectively, these data support the notion that low CYP2D6 activity, caused by genetic polymorphisms or drug interactions, leads to low levels of the active tamoxifen metabolite. The effect of CYP2D6 activity on tamoxifen pharmacokinetics also translates into an effect on clinical outcome. Despite conflicting data in some instances, the majority of retrospective studies suggest that the presence of nonfunctional or reduced-function alleles of CYP2D6 is associated with worse outcome of patients receiving tamoxifen [150,151]. Notably, a recent large retrospective analysis of 1325 patients with early-stage breast cancer treated with adjuvant tamoxifen suggests that compared to extensive metabolizer, those with decreased CYP2D6 activity (heterozygous extensive/intermediate and poor metabolizers) have significantly increased risk of recurrence as well as worse event-free survival and disease-free survival [152]. In addition, *CYP2D6* genotype has also been shown to influence the efficacy of tamoxifen as a chemopreventive agent, whereby tamoxifen-treated women with poor metabolizer phenotype was associated with a significantly higher incidence of breast cancer compared to controls [153]. Findings from these studies support a role for the *CYP2D6* genotype in the activation of tamoxifen and the likelihood of therapeutic benefit from testing for *CYP2D6* genotype.

Aromatase inhibitors (AIs) are also used for the treatment of hormone-sensitive breast cancer in postmenopausal women. AIs inhibit peripheral conversion of testosterone and androstenedione to estradiol. In premenopausal women whose primary

source of estrogen is ovarian production, the AIs have no clinical efficacy. In the United States, two nonsteroidal AIs, letrozole and anastrozole, and one steroidal AI, exemestane, are FDA approved as oral formulation of AIs. Studies indicate that letrozole has more potency to suppress estrogen activity than anastrozole, but it is not known if this difference is clinically relevant [154]. Although AIs can suppress estradiol levels within one day of drug initiation, clinical and/or radiographic evidence of disease response may sometimes lag behind by several weeks [155]. Multiple large randomized studies and meta-analyses clearly showed superior efficacy of AIs over tamoxifen for the treatment of receptor-positive breast cancer in postmenopausal women in metastatic, adjuvant, and neoadjuvant settings [156–163]. Although the effect of hormonal agents is thought to be primarily cytostatic, it is interesting to observe tumor regression in a substantial number of patients with receptor-positive tumors, including clinical and radiographic complete responses (CR) [164].

Abiraterone is a new agent that irreversibly inhibits cytochrome P450 17 (CYP17) α -hydroxylase, a key enzyme converting steroid to testosterone [165]. For patients with advanced prostate cancer, the initial treatment of choice is chemical or surgical castration by luteinizing-hormone-releasing hormone (LHRH) agonist with or without an androgen receptor antagonist. Ketoconazole, which is a less potent α -hydroxylase inhibitor, confers response in castration-resistant prostate cancer (CRPC), but the therapy causes some toxicity as high doses are required for adequate enzymatic suppression. Additionally, it did not improve the overall survival [166]. Abiraterone is specific to α -hydroxylase and is generally well tolerated. In a phase III trial, abiraterone improved the survival of patients with CRPC who had failed docetaxel [167].

15.4.4 Immune-Modulating Agents

Thalidomide was initially sold as a sedative drug in the late 1950s outside of the United States. Owing to its teratogenic effects, thalidomide was withdrawn from the worldwide market in 1962. The exact antineoplastic mechanism of thalidomide is unknown. It demonstrates multiple mechanisms of action including immunomodulatory and antiangiogenic effects. Thalidomide has been investigated for the treatment of many different solid and hematological malignancies. It is currently approved for the treatment of multiple myeloma and is used widely in many countries. Owing to its extreme water insolubility, only oral thalidomide is currently available. Patients with multiple myeloma often have renal impairment at the time of diagnosis. The pharmacokinetics of thalidomide was studied in the population with renal impairment. No dose adjustment is necessary for renal impairment, and no supplementation is required after hemodialysis [168]. Thalidomide is detectable in semen, and therefore, sexually active male patients and their partners should use reliable contraceptive methods to avoid pregnancy [169].

Lenalidomide is an analogue of thalidomide and has more potent immunomodulatory activity. Lenalidomide is also approved for myelodysplastic syndrome with chromosome 5q deletion [170]. Unlike thalidomide, lenalidomide has no sedative effect and causes less peripheral neurotoxicity at therapeutic doses. Renal impairment prolongs the plasma half-life of lenalidomide and significantly increases its AUC [171], and therefore care should be taken when lenalidomide is administered in patients with renal impairment.

15.5 CONCLUSIONS AND FUTURE PERSPECTIVES

The use of oral chemotherapeutic agents has been increased, especially in the recent decade. Besides traditional oral cytotoxic agents, a number of novel oral chemotherapeutic agents with targeted mechanisms of action are available, and many more are under clinical development. An ideal oral chemotherapeutic agent is characterized by a proven efficacy, a good bioavailability and predictable pharmacokinetic profile, and good tolerability. Providing efficacy and tolerability are not compromised; oral chemotherapy offers obvious advantages in terms of patient convenience, improved quality of life, and cost savings. In particular, chronic oral administration is critical for novel molecular targeted agents that generally require a continuous drug exposure and protracted treatment course to achieve antitumor activity. It would be anticipated that oral formulations will become the primary route of chemotherapy administration in the settings of palliative care oncology and adjuvant chemotherapy.

Knowledge and understanding of the pharmacokinetics (i.e., absorption, distribution, metabolism, and elimination) and molecular mechanisms of action and resistance will allow rational use of oral chemotherapeutic agents to achieve optimal efficacy and to avoid undesirable drug interactions and toxicities. Unique to oral agents, absorption is the prerequisite for systemic exposure and activity. Low or variable bioavailability could be due to the first-pass metabolism by CYP3A4 and intestinal efflux by transporters such as ABCB1. Altered activity of CYP3A4 or ABCB1, either caused by genetic or environmental factors (e.g., drug-induced or –inhibited factors), may modulate the bioavailability and pharmacokinetics of oral chemotherapeutic agents that are CYP3A4 or ABCB1 substrates. In addition, concomitant antacid medicines or food can affect the bioavailability of certain oral chemotherapeutic agents (e.g., imatinib and dasatinib). In the era of genomics and personalized medicine, it has been increasingly recognized that the overall response to a drug is determined by the interplay of multiple genes that are involved in the drug disposition (e.g., drug-metabolizing enzymes and transporters) and drug–target interactions (e.g., target receptors and enzymes). The significance of pharmacogenomics in oral chemotherapy is exemplified by 5-FU, tamoxifen, and small molecule TKIs (e.g., gefitinib, erlotinib, and imatinib). Notably, the use of orally bioavailable, small molecule TKIs has revolutionized the treatment of certain cancers and has also expanded the concept of individually tailored cancer treatment. These agents are generally effective in subsets of patients whose tumors have specific molecular traits. Identification of genetic markers predictive of response or resistance will aid in defining the patient subpopulation that most likely derive therapeutic benefit from these novel molecularly targeted agents.

16.1 INTRODUCTION

The development of an individual from a fertilized ovum to maturity radically alters an individual's anatomy and physiology. These changes of size and function, from birth onward, cause significant alterations in the PK of drugs. During the last two to three decades, hundreds of mechanistic and clinical pharmacology studies have been conducted to investigate the impact of ontogeny on the PK and response of drugs in pediatric populations. These research efforts revealed that during child development, several physiological functions change. For example, maturation of the human body

causes changes in (i) liver and kidney size relative to BW (peak value at age one and two years, respectively, and decline toward adulthood as described by Chen *et al.* [1]) (ii) liver blood flow [2]; (iii) plasma protein composition and function [3]; (iv) biosynthesis and levels of sex/growth hormones [4]; (v) expression of drug-metabolizing enzymes (DME) (e.g., temporal switch between CYP3A7 and CYP3A4, FMO1, and FMO3 at birth [5]); and (vi) transporters [6,7]. The age-associated changes in many of these factors have often been implicated in altered drug absorption, distribution, metabolism, and excretion (ADME) and, hence, in drug clearance, pharmacological response, and safety in pediatric population compared with adults [2,8,9]. Furthermore, in the critical ill pediatric patients, that is, pediatric patients, multiple drug therapies for acute and chronic conditions are often administered simultaneously, thus promoting the risk of adverse drug reactions (ADRs) or drug–drug interactions (DDIs). To avoid these from occurrence, understanding the mechanism of drug metabolism and factors that are involved in the hepatically cleared drugs can be critical to ensure the safety and efficacy of drug therapy in human populations, with particular reference to pediatric patients.

16.2 DRUG METABOLISM AND INTERACTION IN RELATION TO PHASE I DRUG-METABOLIZING ENZYMES IN PEDIATRIC POPULATIONS

DMEs play a critical role in the extent of drug biotransformation and thus the hepatic clearance of drugs. Therefore, it is not surprising that ontogeny of hepatic DMEs can significantly alter the clearance of drugs in pediatric populations in relation to that in adults. Drug metabolism mechanisms can be classified into phase I and II reactions, the former involving structural alteration of the drug molecule and the latter consisting of conjugation with another often more water-soluble moiety. Both phase I and II metabolic pathways may be immature at birth and are subject to maturational changes; however, it appears that perinatally, humans are not as functionally adapt with phase II reactions as those of phase I. Several *in vitro* and clinical studies of probe substrates and drugs used in children and adults have revealed that the ontogeny in DMEs and drug transporters is associated with observed significant differences in PK and safety of drugs between children and adults [2,6–15]. Drugs such as omeprazole, theophylline, caffeine, digoxin, cyclosporine, sirolimus, phenytoin, and voriconazole whose clearance is mediated by DMEs and/or drug transporters have different plasma clearance in children than that in adults (Fig. 16.1). The clearance of these drugs in pediatric populations can be the same as in adults, or one population can be higher/or lower than other population can be the same or differ (higher or lower) from that in adults. By elucidating the major clearance mechanism(s) of a drug and the differences and/or similarities between children and adults in DMEs and other physiological factors that affect drug disposition using *in vitro* model systems, one can predict clearance, and thus efficacious and safe dose, of the drug in children based on the known clearance and dose in adults [14,15].

Phase I reactions can be oxidation, reduction, and hydrolysis. Oxidative reactions are frequently carried out by P450 enzymes and have extensively evaluated compared to other oxidative enzymes such as flavin monooxygenases (FMO), which is different from the CYP system. Pediatric populations found to have different metabolic capacity to

Figure 16.1 Plasma clearance of drugs eliminated by metabolism in pediatric populations compared with adults. Clearance values were presented as % of adult values (100%) shown as dashed line. *Source:* Data are published by Edginton *et al.* [8] and Yanni *et al.* [15].

drugs than in adults [4,15,16] as indicated by the difference in clearance or the presence of metabolites in plasma. In addition, there are examples of therapeutic agents that produce metabolites in children that are not present in adults. These metabolites may be responsible for some of the efficacy and/or toxicity observed with drug administration in children: an example is caffeine production in the neonate receiving theophylline, and the metabolite profile generated in children treated with sirolimus [3,17–23]. Although these recent research efforts have focused on the metabolism in relation to ontogeny of P450, other phase I oxidative enzymes such as FMO, monoamine oxidase (MAO), and alcohol dehydrogenase (ADH) [3,5,10] have been evaluated less extensively but are briefly discussed here in this chapter. In addition, the ontogeny of other phase I enzymes that responsible for the reduction and hydrolysis reactions (e.g., aldo and keto reductase, estrases, and peptidase) are mentioned in this section.

16.2.1 Phase I Oxidative Drug-Metabolizing Enzymes in Pediatric Populations

Drug metabolism occurs in almost all body organs, mainly in the liver, small intestine, kidney, and lungs; however, liver is the one that has the greatest metabolic capacity and consequently drug metabolism has been extensively studied in liver. As mentioned earlier, phase I enzymes are responsible for the biotransformation of pharmacologically active drug molecules to more hydrophilic metabolites that are subsequently eliminated by the liver, kidney, or other organs. The age-mediated changes in phase I oxidative DMEs in human liver have been extensively investigated by several groups [5,16,24–26]. Table 16.1 listed changes in the phase I enzymes across the life span as indicated by Hines and McCarver [5]. Much of the existing data that are on the developmental maturation of human hepatic biotransformation pathways are derived

TABLE 16.1 Age-Dependent Changes in Phase I Drug-Metabolizing Enzymes Activity or Protein Expression as Reported by Hines and Mccarver [5]

from *in vitro* hepatic microsomal studies of P450-mediated activity and to a lesser extent from clinical PK studies of probe substrates [2,10,14,25].

16.2.2 Drug Metabolism by Cytochrome P450 Enzymes (P450)

The human P450 superfamily of enzymes is encoded by 59 functional genes that have been divided into 18 families and 42 subfamilies based on divergent evolution. The vast majority of drug metabolism is carried out by 23 enzymes belonging to families 1, 2, and 3. The remaining families are more specialized enzymes involved in the synthesis and degradation of important endogenous molecules. Total P450 content in the fetal liver is 30–60% of adult values. After birth, increases are observed such that total hepatic P450 content approaches adult levels during the first 10 years of life [27,28]. The expression and *in vitro* activity of hepatic P450 enzyme isozymes follow three different patterns in development: (i) enzymes that are expressed in the fetal liver and are active toward endogenous substrates (e.g., CYP3A7) [24]; (ii) enzymes that are expressed in the early neonatal period within hours after birth but minimally expressed in fetal liver (CYP2D6 [29] and CYP2E1, [30]); and (iii) enzymes that are expressed later in neonatal development (CYP1A2 [31], CYP2C [32], and CYP3A4 [24]).

16.2.2.1 Cytochrome P450 1 Family (CYP1). The human *CYP1A1* is the main enzyme responsible for the metabolic activation of polycyclic aromatic hydrocarbons to toxic metabolites in the lung [33]. Using caffeine as a metabolic probe [34], the metabolism of drugs with CYP1A2 in pediatric populations was investigated *in vitro*, and these results were largely consistent with earlier *in vivo* results that measured urinary caffeine metabolites. CYP1A2 catalytic activity and protein levels were observed in postnatal samples with neonates at 4–5% of adult levels, 1–3 months old infants at

10–15% of adult levels, 3–12 months old children at 20–25% of adult levels, and children 1–9 years of age at 50–55% of adult levels. It was found that dietary differences can alter the rate of CYP1A2 maturation, and formula-fed infants CYP1A2 activity is faster than breast-fed infants [35]. It has been known that CYP1A2 is involved in the metabolism of aromatic amines, acetaminophen, imipramine, phenacetin, warfarin, caffeine, and theophylline [36–38]. With regard to the metabolism of caffeine and theophylline, CYP1A2 is involved in all demethylations as well as in ring hydroxylation. These metabolites were not detectable in early neonatal microsomes and became readily identifiable in infants aged one to three months [36–39], although they were present at low levels (30% of the adult level) in infants <one year and attained 50% of the adult value at one year [36]. Levels of CYP1A2 comparable to adults have been found in children three years and older [40,41]. The metabolic profile of caffeine formed by CYP1A2 has been extensively studied by Carrier *et al.* [42] and Pons *et al.* [43] and indicated differential age-mediated changes in the metabolites profile.

The human CYP2A subfamily genes family consists of three members; CYP2A6 is the most important in terms of the metabolism of drugs. Coumarin 7-hydroxylation is a probe metabolic activity for hepatic CYP2A6 [44], but the enzyme also is active toward the oxidative metabolism of nicotine [45] as well as several other protoxics [46]. It has been shown that the urinary excretion of 7-hydroxycoumarin is similar to the adult level in children of 6–13 years of age. Thus, it would appear that hepatic CYP2A6 expression is a postnatal event in liver, while an evidence of prenatal expression in extrahepatic tissues (e.g., from fetal olfactory mucosa) was reported [47].

The human CYP2C subfamily consists of four genes that encode for CYP2C8, CYP2C9, CYP2C18, and CYP2C19 enzymes and the encoded enzymes account for about 18% of total P450 in adult liver [27,28] and are responsible for the oxidative metabolism of ~29% of clinically relevant drugs [9,10]. CYP2C9 is the major hepatic CYP2C enzyme in terms of its content in liver as well as the number of drugs which it metabolizes, followed by CYP2C19 and CYP2C8. CYP2C9 substrates include the anti-coagulant, warfarin; the antidepressant, phenytoin; the nonsteroidal anti-inflammatory agents, diclofenac and ibuprofen; the antidiabetic drug tolbutamide; and angiotensin II receptor blocker, losartan [9,48], while CYP2C19 substrates include the anticonvulsant, mephenytoin [49]; the antidepressant, S-citalopram [50]; the antifungal, voriconazole [51]; and the proton pump inhibitors (PPIs), omeprazole [52–54] and lansoprazole [55].

In the case of the CYP2C family, activity can be significantly faster in children with respect to adults. *In vivo* PK data have indicated that an age-dependent decrease in phenytoin half-life was observed over the first two weeks of life [56]. PK studies in pediatric patients have indicated that the clearance of warfarin in children younger than 12 years was 44% greater than that observed in older children and adults [57]. Clearance of phenytoin that was primarily metabolized by CYP2C9 and to a lesser extent by CYP2C19 was approximately twofold higher in children younger than six years compared with that in adults [58]. The diclofenac 4-hydroxylase was also measured *in vitro* in liver microsomes from different age groups and that indicates the higher activity in children 2–10 years compared with adults [59]. Similarly, clearance of celecoxib in children aged 7–16 years was approximately double that reported for adults [60]. Therefore, as suggested by Anderson and Lynn [9], doses of drugs predominantly metabolized by CYP2C9 may need to be 50–100% higher in children than those given to adults to achieve equivalent therapeutic concentrations.

Contrasting with CYP2C9, there was no apparent change in CYP2C19 levels at birth; however, there was a trend for a near linear increase in the enzyme protein measured in liver microsomes attaining 50–75% of those observed in adults over the first five months after birth. Enzyme levels indistinguishable from adult levels were observed in postpuberty samples. These data were consistent with the (S)-mephenytoin 4'-hydroxylase activities observed in these samples. The *in vitro* activity was also determined as a function of age by Yanni *et al.* [58] and shown in Fig. 16.2a. A comparison of relative CYP2C9 and CYP2C19 levels in individual samples revealed that CYP2C19 is the dominant prenatal CYP2C enzyme, which is gradually relinquished in favor of CYP2C9 at or around birth. These *in vitro* results that described the developmental profile of both CYP2C enzymes were confirmed by the changes in maximal CYP2C9-mediated hydroxylation of diclofenac and CYP2C19-mediated hydroxylation of S-mephenytoin as a function of age of the individual from which the liver microsomes were prepared ($n = 10$ /age group ranging from 20 weeks of gestation to adult).

The PPIs omeprazole, lansoprazole, and pantoprazole that are primarily metabolized by CYP2C19 were studied by Litalien *et al.* [52,54] in children in comparison to adults. The apparent clearance (Cl/F) of PPI appeared to be faster in children than in adults. Higher metabolic capacity in children and the lower bioavailability (F) of PPI observed in children compared with adults were most likely the cause for this finding. There was some evidence of reduced PPI metabolism in newborns. This may partly account for the need in children for variable and sometimes considerably greater doses of PPIs, on a per kilogram basis, than for adults to achieve similar plasma concentrations. Kennedy [4] and Filler *et al.* [17] reported that phenytoin and sirolimus are metabolized by CYP2C9/CYP2C19 and show a higher clearance in children between 2 and 10 years of age than in adults. On the basis of our *in vitro* metabolic study and clinical PK study [15], it has recently been shown that the antifungal drug voriconazole was cleared faster in children <12 years of age than in adults (Fig. 16.1). In addition, Filler *et al.* [17] summarized the PK in children of commonly used immunosuppressive drug

Figure 16.2 *In vitro* age-dependent changes in specific activities of DME. (a) CYP2C9 and CYP2C19 (for presentation, the activities are 10 times the actual activity); (b) CYP 3A4 (for presentation, the activity is 10 times less than actual activity) and CYP3A7 in liver microsomes. Studies were conducted as described by Yanni *et al.* [58] and Yanni [28].

sirolimus (Sir). Sir half-life and mean residence time (MRT) are both shorter than in adults. Similar to situation in adults, there is a profound DDI between cyclosporine and Sir. Of the total metabolite AUC, 77.5% was due to hydroxylated metabolites, while 39-*O*-desmethyl Sir (the main metabolite in adults) comprised only 8.4% of the metabolites. Thus, the authors then concluded that Sir drug disposition vary in children and adolescents with respect to adult patients, most likely because of developmental changes of metabolic enzymes.

The human CYP2D6 subfamily accounting for <2% of total adult hepatic P450 [27], and CYP2D6 is important for the oxidative metabolism of ~12% of clinically relevant drugs [61]. CYP2D6 is highly polymorphic with over 80 different alleles identified to date, including several complete loss-of-function, reduced function, and multiple copy number alleles that are relatively common across most ethnic groups. The well-known polymorphism of CYP2D6 is known to be present in children [62]. The isozyme CYP2D6 contributes to the metabolism of several classes of drugs, such as tricyclic and nontricyclic antidepressants, β -blockers, antiarrhythmic drugs, as well as codeine, cinnarizine, deprenyl, captopril, and ondansetron [62–66], although it is not detectable in fetal liver [63,64]. The *O*-demethylation of codeine to the active moiety, morphine [67], and dextromethorphan to dextrorphan [66], and *O*-demethyl tramadol formation clearance [68] have been used as both *in vitro* and *in vivo* CYP2D6 phenotypic probes. Dextromethorphan *O*-demethylation has been particularly useful in pediatric populations by measuring the urinary ratio of dextromethorphan/dextrorphan as noninvasive method to phenotype CYP 2D6.

CYP2D6 phenotype consistent with its genotype was achieved on average by 15 days postnatal age (PNA) and remained relatively constant over the first six months of life in a cohort of term neonates. CYP2D6 protein was undetectable in 47% of the fetal samples by 30 weeks in gestation, whereas 30% of the samples exhibited values that were at least 5% of those observed in the adult samples. In the 1- to 7-day old newborn age bracket, all samples had detectable CYP2D6 protein, but at a mean level that still was only 5% of that observed in adults. CYP2D6 protein content in this newborn group also was independent of gestational age, suggesting that the development of CYP2D6 is related to the events occur at birth. Thereafter, there was a steady, age-dependent increase in CYP2D6 protein levels such that newborns 7–28 days of age exhibited mean levels that were 30% of adults and infants four weeks to five years, 70% of adults. Dextromethorphan *O*-demethylase activity closely followed this same developmental pattern.

Dextromethorphan *O*-demethylase activity (measured by the ratio of dextromethorphan/dextrorphan) in overnight urine samples [35] was in agreement between the dextromethorphan/dextrorphan ratio and an assigned activity score based on genotype by two weeks of PNA in a cohort of term newborns [68]. There was considerable interindividual variation in dextromethorphan/dextrorphan ratio and Johnson [69] proposed that the discrepancy between the *in vitro* and *in vivo* data on CYP2D6 ontogeny may be largely explained by the added complexity of renal functional maturation that was not considered in the *in vivo* study by Blake *et al.* [35].

The complex interaction of ontogeny, CYP2D6-related pharmacogenetics, and renal elimination clearance were illustrated based on observations tramadol and *O*-demethyl tramadol disposition in infancy [68]. Tramadol (M) hydrochloride is a 4-phenyl-piperidine analog of codeine. *O*-demethyl tramadol (M1) is produced by *O*-demethylation of M by CYP2D6, and it has pharmacodynamic relevance.

N-demethyl tramadol (M2) is produced after *N*-demethylation of M, mainly by CYP3A4. In adults, the urinary log M/M2 ratio reflects CYP3A4/CYP2B6 activity, while the urinary log M/M1 ratio reflects CYP2D6 activity. Tramadol disposition can, therefore, be used as a probe to simultaneously determine the ontogeny of CYP3A4/CYP2B6 and CYP2D6. In early life, the contribution of M, M1, and M2 to overall elimination clearance of tramadol and ratios of M/M1 and M/M2 were assessed in 24-h urine collections during continuous intravenous tramadol administration. Correlations with perinatal characteristics were explored [67]. In neonates and young infants, Allegaert *et al.* [70] reported that the mean log M/M2 was 1.44 compared to an adult phenotypic ratio of 0.47. An inverse correlation between log M/M2 ratio and postmenstrual age (PMA, weeks) ($r = -0.66$, $p < 0.001$, and PNA, days) ($r = -0.5$, $p < 0.01$) was observed with a maturational half-life of the log M/M2 ratio of 16–20 weeks. In a multiple regression model, PMA remained the only significant variable to explain the interindividual variability in log M/M2 ratio. The mean urine log M/M1 was 0.94 compared with an adult phenotypic ratio of -0.1 . Significant correlations of the urine log M/M1 ratio with PMA ($r = -0.73$, $p < 0.0001$) and PNA ($r = 0.56$, $p < 0.001$) were observed. The authors reported that the weak correlations reflect that PMA only in part explains the interindividual variability in log M/M2 or log M/M1.

On the basis of observations in children and adults, it was anticipated that CYP2D6 polymorphisms also contribute to the interindividual variability in *O*-demethylation. The impact of both PMA (either <40 [×] or ≥ 40 weeks [+]) and CYP2D6 activity score on the plasma log M/M1 values is illustrated in patients with an CYP2D6 activity score of 1, 1.5, or 2 (Fig. 16.3a). The lower the log M/M1 value, the higher phenotypic CYP2D6 isoenzyme activity. There is a PMA- and polymorphism-dependent effect.

However, one has to anticipate that besides ontogeny of M1 formation (CYP2D6 related), the final phenotypic M1 concentration–time profile will also depend on renal M1 elimination as clearance mechanisms mature. This results in similar time–concentration profiles from about full-term age onward throughout infancy (Fig. 16.3b), since maturation of glomerular filtration is relatively delayed compared with CYP2D6 ontogeny [68]. On the basis of these *in vivo* observations, we confirm the hypothesis of Johnson [69] that indeed phenotypic CYP2D6 activity depends on ontogeny, CYP2D6 polymorphisms, and renal maturation.

The human CYP3A subfamily consists of four genes that encode for CYP3A4, CYP3A5, CYP3A7, and CYP3A43. It has been shown that CYP3A43 has minimal, if any xenobiotic-metabolizing activity; it is expressed at low levels and no developmental profile of this enzyme has been reported [10]. In contrast, CYP3A4, CYP3A5, and CYP3A7 combined are the most abundant hepatic members of the P450 family and account for nearly 46% of the oxidative metabolism of clinically relevant drugs [61]. These three enzymes share at least 85% sequence identity, a property that has proven to be challenging when these three enzymes protein need to be measured independently by Western blot; however, they exhibit considerable differences in substrate specificity and expression as function of age. In adult liver, CYP3A4 comprises 10–50% of the total P450 enzymes [27]; while CYP3A7 is the dominant enzyme in fetal liver, it is expressed at substantial levels (10–40% of total CYP3A levels) in the adult liver and intestine, depending on the presence of the CYP3A7*1 C allele [72]. A temporal switch was observed between CYP3A7 and CYP3A4 in terms of their expression and activity in liver as function of age. However, CYP3A7 mRNA was detected in fetal liver and

Figure 16.3 Polymorphisms and gestation age effect on interindividual variability of drug metabolism *in vivo*. (a) The impact of maturation on CYP2D6 activity as indicated by plasma log M/M1 values in patients with a CYP2D6 activity score of 1, 1.5, 2, or 3, the lower the log M/M1 value, the higher phenotypic CYP2D6 isoenzyme activity. (b) M and M1 concentration time profile from full-term age onward throughout infancy changes as maturation of glomerular filtration is relatively delayed compared with CYP2D6 ontogeny. *Source*: Figure adapted based on Allegaert *et al.* [67,70,71].

was not detected in adult livers. For CYP3A4 expression, the opposite was observed: it is not expressed in fetal liver but expressed in adult. At the protein level, CYP3A5 was shown to be expressed in a limited number of fetal (1/5; ages not specified) and postnatal (8/20) liver samples with no apparent correlation with age [73] (Fig. 16.4). Consistent with earlier studies, Stevens *et al.* [74] reported that CYP3A5 protein was observed in half of tested samples, but there was no apparent change in enzyme levels as a function of age. As shown in Fig. 16.4, CYP3A7 protein expression in liver microsomes was high but variable in all fetal samples examined; CYP3A4 was detectable in some samples, but at levels that were nearly 100-fold less than CYP3A7. After birth, there was an approximate 50% decline in neonatal CYP3A7 enzyme levels, while little or no change was observed in CYP3A4 level. The CYP3A7 continues to decrease by age, while CYP3A4 continues to increase to reach adult level at age of two years. Hines [10] indicates that CYP3A7 remains the dominant CYP3A enzyme in children up to one year after birth and that CYP3A4 expression increases steadily from birth onward, but only reaches adult levels after one year of age. CYP3A7 activity measured by dehydroepiandrosterone (DHEA) 16 α -hydroxylase in liver microsomes ranged from 0.48 to 1.31 nmol/min/mg in samples from fetal livers and in livers from neonates one to seven-days after birth; the activity then declined steadily to 0.56 nmol/min/mg in neonates between 8 and 28 days to 0.34 nmol/min/mg in infants one to three months

Figure 16.4 Protein expression of CYP3A isozymes, CYP3A4, CYP3A5, and CYP3A7 in liver samples as a function of age. Age ranged from 94 days of prenatal to adult. *Source:* Adapted with permission from Stevens *et al.* [74]. EGA is prenatal age, while PNA is postnatal age.

of age, to 0.17 nmol/min/mg in children from 3 to 12 months of age, and reached the lowest activity (0.07 nmol/min/mg) in adults. In contrast, CYP3A4 activity measured in liver microsomes by testosterone 6 β -hydroxylation was 0.035–0.052 nmol/min/mg, at one year of age and achieved adult levels of 0.120–0.130 nmol/min/mg microsomal protein in children older than one year of age (Fig. 16.4). In this study, the contribution of CYP3A5 activities had not been characterized or considered. However, in a slightly similar approach by Stevens (2003) [74] who considered using differential metabolism of DHEA, 7 β - and 16 α -hydroxylase activity, $V_{\max}$ and K_m parameter values for CYP3A4, CYP3A5, and CYP3A7 were 0.423, 0.0134, and 0.0125 nmol/min/mg protein and 0.433, 0.002, and 1.32 μ M, respectively. DHEA 7 β -hydroxylation was considered a preferential activity of CYP3A4, DHEA 16 α -hydroxylation of CYP3A7, and CYP3A5 levels were determined immunologically. CYP3A4 postnatal ontogeny is consistent with metabolic study of amprenavir in fetal and postnatal liver samples [75] that concluded the fetal-specific expression of CYP3A7, postnatal expression of CYP3A4, while CYP3A5 expression in a limited number of samples during both life stages. These results have been confirmed by the change of *in vitro* enzyme activity as a function of age for both CYP3A7 and CYP3A4 in liver microsomes preparations [59] (Fig. 16.2b).

The clinical implications of the temporal switch between CYP3A7 and CYP3A4 is described in PK of cisapride, a gastroprokinetic agent that was commonly used in pediatric patients with feeding intolerance, apnea, and bradycardia due to gastroesophageal reflux. Owing to a higher than acceptable incidence of cisapride-related QT prolongation in adult patients associated with excessive dose or high plasma levels of parent drug, cisapride was removed from the market and used only through a limited access program for specific diseases, including feeding intolerance in neonates. However, a study by Kearns *et al.* [2] in the same patient population demonstrated a significant increase in QT prolongation not associated with adult risk factors [76]. *In vitro* studies indicated that cisapride is metabolized primarily by CYP3A4, but not by CYP3A5 or CYP3A7 [77]; consequently, it was hypothesized that neonates would show deficient metabolic activity toward cisapride [78]. Consistent with this hypothesis, cisapride *in vitro* metabolism was measured in 50% of the livers from fetus or neonates less than seven days old and the extent of metabolism was low. The hypothesis was further confirmed in an *in vivo* study reported by Kearns *et al.* [2], in which the cisapride terminal elimination rate constant was shown to increase from $\sim 0.02 \text{ h}^{-1}$ in 30-week postconceptional prematured neonates at birth to 0.20 h^{-1} in full term—12-week-old infants. Other kinetic parameters also were consistent with compromised cisapride metabolic clearance in neonates. Thus, the differential substrate specificity of CYP3A4 and CYP3A7 combined with the developmental transition between these two enzymes are implicated with the deficient metabolic clearance of cisapride causing its accumulation that mediates the QT in neonatal patients, particularly those born prematurely, thus the risk for ADRs. Oral clearance of midazolam [79] is also markedly lower in preterm infants relative to that of younger children; it is higher in children aged 2–12 years than in adolescents aged 12–16 years [80]. Similarly, tacrolimus clearance is elevated 2.7- and 1.9-fold among children aged 1.5–5 and 5–12 years, respectively, compared with clearance in those older than 12 years [81]. Similar age-related increases in the clearance of amlodipine [82], clonazepam [83], lopinavir [84], midazolam [79], and saquinavir [85] have been observed. The average weight-corrected doses of drugs predominantly metabolized by CYP3A4 in children must be twofold higher than adult doses to achieve equivalent therapeutic concentrations [4].

Jones *et al.* [86] reported that in recent studies with coumadin (R/S-warfarin) therapy, a complication was observed by interindividual variability in metabolism with CYP3A isoforms that likely contribute to patient responses and clinical outcomes. Despite a significant focus on CYP3A4, little is known about CYP3A5 and CYP3A7 metabolism of warfarin. *In vitro* metabolism studies with recombinant CYP3A4, CYP3A5, and CYP3A7 indicated that these three CYP3A isozymes metabolized R- and S-warfarin with efficiencies that depended on the individual enzymes. For R-warfarin, CYP3A4, CYP3A7, and CYP3A5 demonstrated decreasing preference for 10-hydroxylation over 4'-hydroxylation. By contrast, there was no regioselectivity toward S-warfarin. While all enzymes preferentially metabolized R-warfarin, CYP3A4 was the most efficient at metabolizing all reactions. Individuals, namely African-Americans and children, with higher relative levels of CYP3A5 and/or CYP3A7, respectively, compared with CYP3A4 may metabolize warfarin less efficiently and, thus, may require lower doses and be at risk for adverse DDIs related to the contributions of the respective enzymes.

16.2.3 Drug Metabolism by Flavin-Containing Monooxygenases in Pediatric Populations

The FMOs are major mammalian non-CYP oxidative enzymes [87]. The most abundant adult human liver FMO isozyme is FMO3, which exists at similar level as CYP3A4 [88]. Human FMOs are localized in the endoplasmic reticulum (ER) in intact tissue and are isolated in the microsomal subcellular fraction.

FMOs are encoded by a six-member gene family (FMO1–6) and are involved in NADPH-dependent oxidative metabolism of a wide range of xenobiotics containing nucleophilic nitrogen-, sulfur-, selenium-, and phosphorus heteroatoms. Common therapeutic substrates include tamoxifen, itopride, benzydamine, olopatidine, and xanome-line [89,90]. FMO activity is not readily modulated by induction or inhibition; however, Borbás *et al.* [91] reported that hepatic FMO1 activity increased in a diabetic rat model. The ontogeny of human hepatic FMO exhibits a switch similar to that observed for CYP3A. Expression of FMO1 but not of FMO3 was detectable in fetal liver [92]. In contrast, the transcript of FMO3, but not of FMO1, was detected in adult liver samples. In a study with 240 liver samples ranging in age from 8 weeks of gestation to 18 years postnatal, the highest level of FMO1 expression was observed at 8–15 weeks of gestation [10,93]. FMO1 expression subsequently declined during fetal development and was completely suppressed within three postnatal days by a mechanism coupled to birth but not gestational age. FMO3 expression was observed at low levels at 8–15 weeks of gestation but not in subsequent time periods of fetal development. The FMO3 postnatal expression was found to be highly variable. Most individuals failed to express FMO3 in the neonatal period, but the expression was detectable by one to two years of age, as listed in Table 16.2.

It has been reported that FMO enzymes are subject to interindividual variation. Single nucleotide polymorphisms (SNPs) are associated with large differences in enzyme activity in some human subjects, mostly among Japanese and African-American populations [94]. Some FMO3 mutations have been associated with trimethylaminuria (TMA), a rare metabolic disorder caused by the inability to *N*-oxygenate dietary-derived TMA. The therapeutic implication of ontogeny in relation to FMO has not been as well documented as for P450 enzymes. To date, there are only few PK

TABLE 16.2 Age-dependent Changes in Phase I Drug-Metabolizing Enzymes Activity or Protein Expression as Reported by McCarver and Hines [26]

Gene	Prenatal Trimester			Neonates	One Month– One Year	1–10 Years	Adult
	1	2	3				
GST α 1/ α 2	+	+	+	+	+	+	+

+, activity or protein detectable; –, no detectable activity or protein; ?, not determined.

studies that describe the role of FMO in the disposition of drugs in children and pediatric populations compared with adults. Orenstein *et al.* [95] reported that ranitidine, which is predominately metabolized by FMO, had a clearance value in children that was similar to the reported for adults. Impaired *in vivo* metabolism of benzydamine (marker substrate for FMO3) was found in pediatric patients with deficiency of FMO3 [96].

16.2.4 Drug Metabolism by Monoamine Oxidases in Pediatric Populations

MAOs are oxidative enzymes located in the mitochondria and involved in the metabolism of endogenous and exogenous compounds [97]. The ontogenetic development of MAO-A and MAO-B in the frontal cortex of human brain has been previously studied by Kornhuber *et al.* [98]. The temporal switch that has been reported with CYP3A and FMO was also found with MAO. MAO-A activity was found to be very high at birth and then decreased rapidly during the first two years of life and remained unchanged onward, while the MAO-B activity was low at birth, remained unchanged during early childhood, and then increased with age. The ontogeny-mediated changes of drug metabolism by MAO-A/B in human tissues have not been investigated, and it could be useful if the age-mediated changes in the metabolism by MAO of tyramine and tyramine, containing foods such as cheese, to be investigated in the gut.

16.2.5 Drug Metabolism by Alcohol Dehydrogenases in Pediatric Populations

ADH is the rate-limiting enzyme responsible for the biotransformation of ethanol. Early PK data for ethanol in neonates clearly support the poor metabolism of ethanol and its plasma accumulation and reduced clearance confirming developmental immaturity in ADH activity [99,100]. It would appear that by 12–30 months of PNA, ADH activity reached equal to or greater than that observed in adults [101,102] (Table 16.1). ADH3, also termed *formaldehyde dehydrogenase* or *S-nitrosoglutathione reductase*, plays a critical role in the enzymatic oxidation of formaldehyde and reduction of nitrosothiols that regulate bronchial tone. Considering reported associations between formaldehyde vapor exposure and childhood asthma risk, and thus potential involvement of ADH3, Thompson *et al.* [102] reviewed the ontogeny, distribution, and regulation of mammalian ADH3. The authors reported that multiple biological and chemical stimuli influence expression and activity of ADH3, including the feedback regulation of nitrosothiol metabolism and concluded that the levels of ADH3 correlate with, and potentially influence, bronchial tone. Hence, ADH3 ontogeny function relative to the effects of formaldehyde, as well as other chemical and biological exposures, might be critical to childhood asthma.

Brent [103] recently investigated the treatment of pediatric patients with metabolic acidosis caused by the catalysis of ADH to the ingested ethylene and diethylene glycol, butoxyethanol, and methanol by using drugs such as fomepizole. Fomepizole as well as ethanol are potent inhibitors of ADH; thus, they reduce the generation of toxic metabolites causing increased anion gap. The median age of these cases was 5.5 years old. All 10 patients had resolution of their metabolic acidosis. The half-times of ethylene glycol elimination ranged from 9 to 15 h during fomepizole therapy, which is faster than the 19.7 h reported in adults. The two patients who ingested diethylene

glycol or butoxyethanol all recovered. Plasma fomepizole concentrations were measured in three cases and were found to be therapeutic with apparent Michaelis–Menten kinetics, having a zero-order elimination rate of 0.6–1 mg/L/h at higher concentrations and a first-order elimination with an apparent elimination half-time of 3.9 h at lower concentrations. In conclusion, the author reported that fomepizole dosage in pediatric population is the same as used for adults.

16.2.6 Metabolism by Phase I Reductive Enzymes in Pediatric Populations

Phase I reductive enzymes-mediated drug metabolism is poorly investigated. One of these enzymes is the cytosolic aldo-ketoreductase that reduces carbonyl group-containing drugs. The enzyme is present in the liver, other tissues, and erythrocytes. It metabolized hypolipidemic drugs, such as fenofibrate, and antitumor drugs (e.g., the anthracyclines) [104,105]. Ketoreductase activity is also involved in the metabolism of prostaglandin E1 (PGE1), which is used for the treatment of peripheral arterial occlusive diseases [106]. Idarubicinol, the alcohol product of keto reductase biotransformation of idarubicin, was found in the cerebrospinal fluid (CSF) of pediatric patients receiving the drug in a phase I leukaemia study [107,108]. In the absence of additional information, it is difficult to conclude whether the presence of the reduced metabolite in the CSF is due to higher peripheral and/or central ketoreductase activity in the pediatric patients or to a different distribution of idarubicin and/or idarubicinol in this population. A 13,14-dihydro-15-ketoprostaglandin E1 is formed as an intermediary metabolite of PGE1; this metabolite is further reduced by a 15-ketoreductase to 13,14-dihydro-prostaglandin E1, the active compound. Interindividual variation in the enzymatic 15-ketoreduction of 13,14dihydro-15-ketoprostaglandin E1 was reported in human liver and children aged ≤ 10 years had a significantly lower activity than those aged ≥ 13 years [109]. The activity of such a ketoreductase has been thought to be related to sexual maturity [108,110].

16.2.7 Phase I Hydrolytic Enzymes in Pediatric Populations: The Role of Extrahepatic Metabolism

Hydrolytic enzymes, such as esterases, might display age-dependent changes in their functions. *In vivo*, drug such as propacetamol can serve as probe to assess esterase activity since it is a prodrug that hydrolyzed to paracetamol. A study by Anderson *et al.* [111] demonstrated that by predicting hydrolysis half-life in pooled population PK study in neonates, toddlers, and children, an assessment of potential age-dependent maturation of esterase during childhood can be made. The authors thereby concluded that there was no age-dependent effect on hydrolysis half-life, suggesting that esterase is already mature at birth. However, hydrolysis half-life depends on both clearance and distribution volume characteristics. Other reports showed that esterase activity is reduced in the newborn [111–112], but a rapid increase in its activity, for example, plasma pseudocholinesterase and arylesterase activity occurred from 28 weeks gestation to 1 year of age with no significant changes in activities from those of adults occurring after one year. However, the erythrocyte acetylcholinesterase levels increased significantly between 40 weeks gestation and 1 year of age [112]. Plasma esterases in infants hydrolyzed procaine hydrochloride and the insecticide paraoxon with lower rate than children older than one year and adults, although the hydrolysis rate was

faster in the mature infants than in the premature. Drugs administered in the form of an ester that require metabolism to the microbiologically active form *in vivo*, for example, erythromycin estolate and chloramphenicol palmitate, might be incompletely hydrolyzed in neonates [113]; thus, low plasma concentration of acid metabolite will be achieved and necessitate drug concentration monitoring to ensure therapeutic plasma concentrations are obtained [114]. Similarly, in a study on serum aspirin–esterase activity in epileptic patients [115], significant differences have been found in serum aspirin–esterase activity between children and adults, although in this case, the epileptic children were found to show significantly higher levels of hydrolytic activity than adult patients or control healthy subjects.

Different from esterases, peptidase has been taking a role in the treatment of children and adolescent psychiatric patients who suffer from attention deficit hyperactivity disorder (ADHD). Lisdexamfetamine (LDX) was approved by the Food and Drug Administration (FDA) for treating ADHD in children in early 2007. LDX is a prodrug, which when orally ingested is converted to L-lysine and active D-amphetamine, which is responsible for its therapeutic activity. The hydrolytic mechanism occurs by the catalysis of peptidase in blood and tissues. This unique formulation may lead to a possible reduction of the abuse potential by circumventing the first-pass metabolism. The solubility and conversion for LDX to D-amphetamine and absorption of LDX (mediated by uptake drug transporters PEPT) is not affected by variations in gastric pH, while the PK of D-amphetamine were found to be similar in pediatric and adolescent ADHD patients and healthy adult volunteers [116].

16.3 DRUG METABOLISM AND INTERACTION IN RELATION TO PHASE II DRUG-METABOLIZING ENZYMES IN PEDIATRIC POPULATIONS

16.3.1 Role of Glucuronosyltransferase Enzymes (UGT) in the Metabolism and Interaction of Drugs in Pediatric Populations

The biotransformation of many drugs, such as chloramphenicol and novobiocin, undergo critical changes during the perinatal period. Glucuronidation appears to be particularly impaired in early neonatal life, and this impairment does play a role in the genesis of neonatal “physiologic” jaundice [117,118]. Activity toward estrone was present in the fetal liver at 30% of adult values, while activities toward bilirubin, androsterone, testosterone, 1-naphthol, 2-aminophenol, 4-nitrophenol, and morphine were all present in fetal and term liver at values of <14% of those of adults [119–121]. Bilirubin glucuronidation that carried out by the isozyme uridine 5′-diphosphate glucuronosyltransferase (UGT)1A1 was particularly low in fetal liver, <1% of the activity of the adult liver [119] as well as the rate of morphine glucuronidation that catalyzed by UGT2B7 [122] was 6- and 10-fold lower in fetal liver microsomes samples than in the adult [121]. Activity toward all other substrates measured developed after birth [118] and glucuronidation may not approach adult values until three to six months of life [118], one year [123], three years [124,125], or even later [124–126] (Table 16.2). As glucuronidation is markedly deficient in most premature infants and some full-term babies [127], the accumulation of high concentrations of unchanged chloramphenicol may occur in a

neonate receiving recommended doses based on BW, resulting in serious toxicity (gray baby syndrome). Doses adjustment based on PK studies led to more precise dosage regimens on the basis of weight, gestational, and PNA. Filler *et al.* [17] summarized the PK in children and youths of commonly used immunosuppressive drug, mycophenolate mofetil (MMF). Regarding MMF, the authors were unable to demonstrate age dependency of MMF in combination with cyclosporine. By contrast, there was an inverse relationship between age and the dose-normalized mycophenolate (MPA) area-under-the-time-concentration curve (AUC) in children who received concomitant tacrolimus (Tac). Dose-normalized MPA AUCs were higher than commonly observed in adult patients. The authors hypothesized that the age dependency is related to developmental changes in the expression of the UDP-glucuronosyltransferases. In conclusion, MMF drug disposition varies in children and adolescents from adult patients, most likely because of developmental changes of biliary transporters and metabolic enzymes.

As CYPs, there are several isozymes of glucuronosyl transferases and the developmental changes of one isozyme can be different compared to the others. Therefore, characterization of glucuronidation reactions should be considered and caution should be taken in consideration when extrapolating information on developmental changes obtained with one isozyme to the others. Morphine is extensively metabolized by glucuronidation with the formation of both 3- and 6-glucuronides (M3G and M6G). M6G has been shown to be a potent analgesic in clinical studies in human subjects [128]. The metabolism of morphine was studied in children and premature neonates [129]. All the neonates and children had detectable concentrations of M3G and M6G. The M3G/morphine and M6G/morphine ratios were significantly higher in children than in neonates, thus suggesting that morphine glucuronidation capacity is enhanced after the neonatal period, although there was no difference in the M3G/M6G ratio in children and neonates, indicating a parallel development of both glucuronidation pathways that were carried out by the same isozyme [130]. It has been documented that the additional impact of PNA (first 10 days of postnatal life) on glucuronide formation, irrespective of the PMA. On the other hand, acetaminophen glucuronidation is carried UGT1A6, but UGT1A1 and UGT1A9 are also involved [131]; a relative deficiency in glucuronide conjugation of this drugs is still observed in children of 7–10 years compared with adults [126].

The phenotypic impact of glucuronidation on elimination clearance of a compound also depends on the availability of other elimination routes, either metabolic (hepatic, e.g., sulfation) or elimination (mainly renal). To illustrate the relevance of this concept, it is worth comparing the PK of acetaminophen with the PK of propofol in early neonatal life [132]. Anderson *et al.* [133] demonstrated that elimination clearance for intravenous acetaminophen depends on PMA, without any additional impact of PNA. Besides PMA, PNA is also a covariate of the proportion of glucuronidated acetaminophen to overall acetaminophen metabolic elimination, reflecting impaired glucuronidation (Fig. 16.5a). However, impaired glucuronidation activity is compensated by a phenotypically higher sulfation metabolism and even renal elimination of the mother compound, acetaminophen [133]. As a result, acetaminophen clearance only depends on PMA without any additional impact of PNA [134].

In contrast, propofol is highly lipophilic and undergoes metabolic elimination clearance. The disposition of propofol has been extensively studied in different populations

Figure 16.5 Glucuronidation of as a function and impaired glucurination at birth. (a) Demonstrated elimination clearance for intravenous acetaminophen depends on postmenstrual age, without any additional impact of postnatal age. Besides postmenstrual age, postnatal age is also a covariate of the proportion of glucuronidated acetaminophen to overall acetaminophen metabolic elimination, reflecting impaired glucuronidation. (Data summarized in Anderson *et al.* [133]) (b) Age-dependent differences in propofol clearance reflect quantitative or qualitative differences in propofol metabolism. In adults, propofol undergoes either glucuronidation [mainly through UDP-glucuronosyltransferase (UGT) 1A9, resulting in propofol glucuronide, PG] or hydroxylation [mainly cytochrome P450 (CYP) 2B6, resulting in 1- or 4-quinol, 1-Q, and 4-Q] with subsequent glucuronidation [(1-quinol glucuronide (1-QG), 4-quinol glucuronide (4-QG)] or sulfation [4-quinol sulfate (4-QS)], respectively; PG is the most contributing metabolite, whereas in neonates, the contribution of quinol metabolites is much more relevant to overall metabolism in neonates compared with glucuronidation (as described by Allegaert *et al.* [71]).

of adult and pediatric age, but observations in neonates are limited. Propofol clearance in neonates is significantly lower compared with children and displays extensive variability. Covariates of propofol clearance in neonates are PNA and PMA [133].

Since propofol clearance exclusively depends on biotransformation, it is reasonable to anticipate that age-dependent differences in propofol clearance reflect quantitative or qualitative differences in propofol metabolism. In adults, propofol undergoes either glucuronidation [mainly through UDP-glucuronosyltransferase (UGT) 1A9, resulting in propofol glucuronide, PG] or hydroxylation [mainly cytochrome P450 (CYP) 2B6, resulting in 1- or 4-quinol, 1-Q and 4-Q] with subsequent glucuronidation [(1-quinol glucuronide (1-QG), 4-quinol glucuronide (4-QG)], or sulfation [4-quinol sulfate (4-QS)], respectively. After bolus administration (3 mg/kg) in adults, PG is the most contributing metabolite while urinary excretion of unchanged propofol only marginally (<1%) contributes to propofol clearance. In neonates, the contribution of quinol metabolites is much more relevant to overall metabolism in neonates compared to glucuronidation (Fig. 16.5b) [135]. Since CYP2B6 ontogeny is also relatively delayed, this pathway cannot compensate for the PNA-dependent glucuronidation pathway and in the absence of other (primary elimination pathways), this results in overall low propofol clearance in neonates, even more pronounced in early neonatal life (< eight days postnatal).

16.3.2 Role of Sulfotransferase (SULT) Enzymes in the Metabolism and Interaction of Drugs in Pediatric Populations: Role of Extrahepatic activity

The sulfotransferase (SULT) gene family encodes at least 11 distinct enzymes that are expressed in the cytosol and they catalyze the sulfate conjugation of a variety of endogenous (e.g., hormones and neurotransmitters) and exogenous chemicals (e.g., drugs). SULTs and glucuronosyltransferases may have overlapping substrate specificities and thus complimentary biotransformation. Sulfoconjugation can overcome the impairment of glucuronidation in the pediatric population as this reaction is practically mature at birth [51,132,133]. When SULT with 2-naphthol as a substrate was investigated in human adult and fetal liver, the activity in the adults was approximately threefold higher than that in the fetuses [136] (Table 16.2). However, in fetal kidneys and gut, the activity was twice as high as in the liver, whereas it was comparable to the hepatic activity in the lungs and the adrenals [71]. The sulfate pathway is the dominant metabolic route for salicylamide and paracetamol in infancy and childhood [126]. Similarly, the neonate can use sulfate conjugation as an alternative route for morphine metabolism before glucuronidation develops [71,137]. As CYPs and UGTs, there are several forms of SULTs and the developmental pattern of these isoforms can be different, as shown for two forms of phenolsulfotransferases, SULT1A1 (substrate 4-nitrophenol) and SULT1A3 (substrate dopamine) [138–140]. SULT1A3 develops earlier than SULT1A1 and its activity is threefold higher in the human fetal compared with adult liver. At midgestation, SULT1A1 activity is lower in the human fetal than the adult liver [141]. Gilissen *et al.* [142] demonstrated the presence of SULT1A1 activity as early as 15-week gestation and failed to see any significant changes in activity during gestation or at 1 or 1.5 years PNA. Thus, SULT1A1 activity increases in the adult after quite late in childhood development or perhaps in early adult. Barker *et al.* [143] examined the age-mediated change of SULT2A1. In the liver, both activity and protein levels were low to nondetectable before 25-week gestation but then increased substantially during the latter half of gestation to approach adult levels in the neonate. A similar SULT2A1 developmental expression pattern was observed in the kidney, although activity in this tissue was 10% of that observed in the liver.

16.4 CRITICAL PHYSIOLOGICAL PARAMETERS THAT PLAY ROLE IN DRUG METABOLISM, EXPOSURE, AND INTERACTION IN PEDIATRIC POPULATIONS

In addition to the complexity of ontogeny, other covariates [144] and many physiological parameters also change with age and these could alter the drug metabolism and, hence, drug dispositions among humans.

16.4.1 Protein Binding

The use of the well-stirred model to calculate clearance requires a consideration of the age-related changes in hepatic blood flow (Q_H) and unbound fraction (f_u) as shown in Equation 16.1. Therefore, the values of Q_H and f_u , specific for the age group, must be used to obtain estimates of *in vivo* hepatic metabolic drug clearance in specific pediatric groups. It is known that plasma protein levels are lower in the newborn gradually

increase with age. At birth, human serum albumin (HSA) concentrations are close to adult levels (75–80%), while α_1 -acid glycoprotein (AAG) is initially half the adult concentration. McNamara and Alcorn [13] have reported that age-dependent changes in f_u can be estimated for a particular pediatric age group on the basis of known pediatric plasma protein-binding ontogeny data. This approach scales the unbound fraction from adult to pediatric subjects on the basis of a correlation between unbound fraction and the relative levels of the major plasma-binding proteins (albumin and AAG) assuming a constant value for binding affinity between adults and pediatric subjects according to Equation 16.2:

$$\text{Calculated } in \text{ vivo } Cl_{\text{plasma}} = \frac{Q_H \times f_u \times \text{intrinsic } Cl'_{\text{plasma}}}{Q_H + f_u \times \text{intrinsic } Cl'_{\text{plasma}}} \quad (16.1)$$

$$f_{u,\text{infant}} = \frac{1}{1 + \frac{P_{\text{infant}}(1 - f_{u,\text{adult}})}{P_{\text{adult}} f_{u,\text{adult}}}} \quad (16.2)$$

where P_{infant} is the molar plasma protein concentration in infants and P_{adult} is the molar plasma protein concentration in adult. The authors showed that the extent of drug binding to HSA in children is close to that in the adult; however, the extent of protein binding for drugs largely bound to AAG increased with age. As listed in Table 16.3, for values published by the authors, the observed f_u versus predicted f_u values in infant and compared the results to those in adults for several drugs bound to HSA or AAG. From the results in Table 16.3, for all drugs, whether bound to HSA or AAG, f_u appeared to be different in children than in adults, but the difference did not exceed more than threefold. Since AAG is also an acute phase protein, a postoperative increase has been described. It should be noted that, in addition to lower HSA concentration, bilirubin and free fatty acids may influence the extent of binding of some drugs in the newborn. This binding is competitive in nature, and a highly bound drug (e.g., rocephine) is contraindicated in neonates because of displacement of (endogenous) unconjugated bilirubin, potentially resulting in kernicterus. Nau *et al.* [136] reported that the free fatty acid elevation after birth results in increased free fractions of diazepam and its main metabolite. Hyperbilirubinemia is also found to reduce the binding of a number of acidic drugs. Elevated free fatty acids and bilirubin may explain some of the intersubject variability for a given drug within a population of infants. The effect of elevated bilirubin, free fatty acid, or lower HSA in neonatal serum may explain the difference between f_u in neonates and adults, but it is clear that caution should be exercised when using predictive models in determining f_u in pediatric populations. In a study with antifungal drug micafungin, *in vitro* serum-binding study in serum from neonates using equilibrium dialysis, f_u of micafungin was found to be eightfold higher than that in adult serum [145]. This indicated that mechanistic studies of drug serum binding as a function of age should be conducted, especially with drugs that are extremely lipophilic.

16.4.2 Hepatic Blood Flow

Developmental changes in hepatic blood flow (Q_H) are poorly understood. Age-associated changes in Q_H may influence hepatic clearance when hepatic elimination is limited by the rate of hepatic drug transport and not enzyme activity [9]. With blood flow rate-limited drugs, developmental changes in metabolic enzymes will impact

TABLE 16.3 Difference between Children and Adults in Extent of Drug Binding to Either α_1 -Acid Glycoprotein (AAG) or HAS Data Were Reported by McNamara and Alcorn [13]

Age	Major Binding Protein (% of Adult)	Drug	Child		Adult f_u

hepatic clearance only when the enzyme activity is exceedingly under developed such as when enzyme activity becomes the rate-limiting factor for overall drug elimination. For blood flow rate-limited drugs, the use of an adult parameter or allometric scaling model for Q_H may not be appropriate for newborns and a significant portion of hepatic portal blood flow will be shunted away from the functioning hepatocytes in the first or second week of life. The Q_H values according to population age and gender are listed in Table 16.4a.

16.4.3 Liver Size Relative to Body Weight

The major organs responsible for drug clearance are the liver (and kidneys). Their developmental changes in relative size affect the PK of drugs in an age-dependent manner. The most prominent observation is that the mass of liver (and kidney) relative to age is several-fold greater in preschool-age children than in young adults [10] (Fig. 16.6a). On the basis of this observation, the ratio of liver to body mass is not a constant parameter; it is considerably greater in infants and young children than in adults. This may contribute to greater hepatic clearance in children; however, the size alone can account for some, but not all the developmental differences observed in drug clearance between adults and children [147,148]. Scaling by normalization to a 70-kg individual using the three-fourth power allometric rule was used in the prediction of pediatric data based on adults data, adjusted for the differences in liver size relative to body mass in pediatric versus adult individuals [149]. Because the weight ratio of different organs may vary with age, it is recommended that age appropriate parameters ([146]; Table 16.4b) to be also used for calculating the clearance and estimation of doses in children from adult data. Yanni *et al.* [15] determined the factors responsible for the higher clearance of the metabolically cleared antifungal drug voriconazole in children age two to eight compared with adult and concluded that the ratio of liver size to body mass seems not to contribute to the difference in clearance (although the scaling factor that is the product of milligram of microsomal protein and ratio of gram liver to kilogram body mass was statistically different, greater in children compared to adults) [69].

16.4.4 Milligram Microsomal Protein per Gram Liver

Recent studies have shown that microsomal protein content also changes with age. Studies using a set of pediatric samples suggested an increase in microsomal protein content from birth (26 mg/g liver) to the average microsomal protein content of a 30 year old (40 mg/g liver), which then declined to 31 mg/g liver for the average 60 year old [150]. When correlation analysis was performed between observed and calculated clearance for 21 different drugs in adults at different milligram microsomal protein per gram of liver (MPPG) (77, 45, 21, and 34 mg/g), the best correlation was found when MPPG is 34 mg/g (Fig. 16.6b2). MPPG values determined with samples from pediatric livers indicated that MPPG increases with age, the mean MPPG value for young infants less than one year of age was as low as 10 mg/g, while the mean value for children <10 years of age was 23 mg/g, and for adults, the mean value was 31 mg/g (Fig. 16.6b). It is clear that the change in MPPG with age has an impact on altering the scaling factor value and the hepatic clearance of drugs in human population, especially between young children and adults.

16.4.5 Uptake and Efflux Drug Transporters

In addition to DMEs, transporter-mediated processes also play critical roles in the overall disposition of numerous drugs in clinical use. Besides their roles in xenobiotic transport, drug transporters often mediate important physiologic functions via transport of endogenous substrates such as amino acids, bile acids, and hormones. Transport proteins are known to affect drug bioavailability and clearance and, most importantly,

Figure 16.6 Changes in physiological parameters as a function of age. (a) Changes in relative liver and kidney mass as percentage of body weight from infancy to young adulthood (Adapted with permission from Chen *et al.* [1]). (b-1) Box plot of MPPG values measured in infants, children, and adults based on results listed in [28]; (b-2) analysis of observed oral clearance of 21 drugs and predicted values calculated by using MPPG value of 34 mg/g liver. *Source:* Adapted with permission from Barter *et al.* [150]).

efficacy in target organs [151]. Drug transporters are expressed in all body organs; however, they are most extensively investigated in those organs that are responsible for drug disposition and clearance such as the liver, kidney, and intestine [152,153]. The localization of major transporters and their role in the disposition of drugs and endogenous biomarkers are also reported by these investigators. Drug transporters can be generally separated into two major classes: uptake and efflux transporters. The role of uptake transporters is to facilitate the translocation of drugs into cells. Major members of the uptake transporters are the organic anion-transporting polypeptide family (OATP, *SLCO*), sodium–taurocholate cotransporting polypeptide (NTCP, *SLC10A1*), organic anion transporter (OAT, *SLC22A*), and organic cation transporter (OCT, *SLC22A*) families. Among the uptake transporters, certain transporters have been shown to exhibit both influx and efflux properties, while others act only as uptake transporters. For example, the OATPs are primarily considered uptake transporters that mediate transport via sodium-independent mechanisms in contrast to sodium-dependent uptake transporters such as NTCP. Efflux transporters export drugs from the intracellular to the extracellular milieu, often against high concentration gradients. The ABC efflux transporters are P-glycoprotein (P-gp, *ABCB1*), the bile salt export pump (BSEP, *ABCB11*), the multidrug resistance associated (MRP, *ABCC*) protein family, and the breast cancer resistance protein (BCRP, *ABCG2*). The efflux transporter, P-gp, has different functions in various tissues. For example, its expression is associated with a decreased absorption of substrate xenobiotics in the gut, which leads to lower bioavailability, whereas it decreased the penetration of substrate xenobiotics into the brain across the

blood–brain barrier, reducing the CNS effect or unfavorable CNS toxicity. However, in the liver and renal tubules, P-gp facilitates the excretion of substrate xenobiotics into bile and urine, respectively [152–154]. As in the other organs, drug transporters are either localized in the basolateral membrane or apical (canalicular) membrane to enhance the uptake from blood into the hepatocytes or the efflux into bile.

In humans, very little information is available on the ontogeny of drug transporter-mediated drug disposition and its effect on the extent of drug metabolism. Johnson and Thomson [6] and Yanni *et al.* [145] have recently presented results from *in vitro* investigations that described age-related changes in expression of transporters in hepatic and extrahepatic human tissues and provided an insight of the impact of these changes of the drug transporter functions on altering drug disposition.

In humans, P-gp expression in the central nervous system from neonates born at 23–42 weeks of gestational age suggested a pattern of localization similar to that in adults [2]. However, the level of expression of P-gp appeared to be lower than that in adults. Johnson and Thomson [6] in their review article reported that the mRNA and protein expression of P-gp in normal duodenal biopsies from children aged 1 month to 17 years was not statistically different and concluded that the age has no effect on the expression level. In addition, P-gp mRNA and protein in human were detected as early as 11–14 weeks of gestation in the liver and kidney but were detected only in the intestines of full-term infants. In contrast to these results, others have demonstrated an age-dependent increase of intestinal expression of MDR1, where a fourfold higher expression of MDR1 was observed in young adults than in neonates. These data indicated a postconception age-related maturation of these transporters. This conclusion was supported by a clinical study of cyclosporine by Fanta *et al.* [155] who showed that while the bioavailability of cyclosporine was independent of genetic polymorphism in MDR1 in younger children than eight years, genetic polymorphism in MDR1 codes for P-gp in children older than eight years caused 1.5-fold higher bioavailability of cyclosporine in noncompetent MDR1 subjects than in competent MDR1 subjects. These results revealed the presence of active P-gp function in children older than eight years but not in younger populations. However, when immune staining of MDR1 in children liver (less than two years of age) was compared to that in adults, localization and expression levels were similar. In humans, it has been reported that oral clearance of fexofenadine depends on the efflux transporters P-gp and organic anion-transporting peptides in the gastrointestinal tract [156]. A population PK analysis of fexofenadine in infants and children aged 6 months to 12 years revealed no significant effect of age on oral clearance of the drug [157]. This clinical data indicate that the functions of both OATP uptake and P-gp efflux transporters might mature as early as six months of age. It has been found that P-gp, MRP1, and MRP2 act synergistically with P450 to protect the organism from toxic compounds. Digoxin serves as an excellent example for ontogeny of renal elimination. The drug is not only excreted by glomerular filtration but also extensively secreted by the tubular cell by P-gp. Young children need threefold higher doses of digoxin per kilogram BW than adults. This difference cannot be explained by GFR changes alone, as GFR in young children is twofold higher than in adults per kilogram. The secretion of para-aminohippurate (PAH) demonstrates that organic anion secretion is low at birth in humans and other mammals, increases over the first few weeks of neonatal life, and then declines to adult levels [158]. This increase in organic anion secretion is disproportionate to the increase in kidney mass and is thought to reflect the specific maturation of the organic anion transport system

rather than the growth and development of the kidney itself. A wide variety of drugs are transported by OATs, including ACE inhibitors, angiotensin receptor blockers, β -lactam antibiotics, antiviral drugs, and NSAIDs, and have been prescribed to children at all ages with no reports on toxicity, implying that OATs are fully functional [1].

16.5 DRUG CLEARANCE AND EXPOSURE IN RELATION TO DRUG METABOLISM IN PEDIATRIC POPULATIONS

The changes in phase I and II DMEs as a function of age is one of the factors that affects drug clearance in pediatric populations and that has been extensively investigated *in vitro* by measuring expression and activities in tissues from different age groups [2,14–16,24,69]. Furthermore, it has been investigated in the clinical setting (*in vivo*) by comparing the hepatic metabolic clearance of DMEs probe substrates in various age groups and *in silico* using physiologically based pharmacokinetic (PBPK) models [11,12,159–161]. These studies showed that age-associated changes in phase I/II DMEs can have a significant impact on PK/pharmacodynamics (PD) of drugs whose elimination is predominately dependent on the metabolic pathway mediated by those enzymes. Accordingly, altered dosage regimens were recommended to optimize drug exposure and achieve therapeutic efficacy and safety in children [160,161]. These studies have improved understanding on the differences in PK/PD of drugs between children and adults during the last two decades, and as a result, a child is no longer considered a “miniature” adult and pediatric dosing regimens are now adjusted based on maturity of body functions, drug clearance, and exposure [160,161] and not just by simplistic (per kilogram) or more complex (body surface area, BSA, $\text{kg}^{0.75}$) scaling of an adult dose. However, more research in this field is warranted to improve our ability to estimate safe and efficacious doses in different pediatric subpopulations from our knowledge of the adult doses [69].

In the past, therapeutic or toxicological assessment in pediatric populations was done only on the basis of an approximate linear relationship between PNA and BW or surface area. Hence, dose was adjusted on the basis of age-associated differences in BW or BSA [18] according to Equations 16.3 and 16.4:

$$\text{Dose}_{\text{child}} = \text{Dose}_{\text{adult}} \times \frac{\text{BW}_{\text{child}}}{\text{BW}_{\text{adult}}} \quad (16.3)$$

$$\text{Dose}_{\text{child}} = \text{Dose}_{\text{adult}} \times \frac{\text{BSA}_{\text{child}}}{\text{BSA}_{\text{adult}}} \quad (16.4)$$

These approaches might have caused underpredicting of therapeutic dose, thus therapeutic failure, or overpredicting the dose that might have caused drug-related toxicity. It is known that the total exposure to a drug determined by the area under the plasma concentration versus time curve is not only determined by the bioavailable dose fraction (F) but also by the efficiency of the elimination mechanisms as measured by the systemic clearance (Cl_s) as shown in Equation 16.5:

$$\text{AUC}_0^\infty = \frac{F \times \text{Dose}}{\text{Cl}_s} \quad (16.5)$$

Therefore, age-dependent differences in bioavailability and clearance that altered by the extent of metabolism (if metabolism is the mechanism of elimination) usually account for differences in plasma concentrations and exposure among age groups. Scaling of a dose by simple adjustment per kilogram basis or surface area does not consider the developmental changes as a result of both growth and maturation of the physiological and biochemical processes governing bioavailability and clearance.

Clearly, because age-associated changes in body composition and organ function are not linear and can be discordant during the first decade of life, those simplified dosing approaches across the span of childhood or in various disease states may account for 90% of ADRs among hospitalized children as it was reported by Johnson [6]. Thus, therapy must be optimized by assessing the developmental differences of drug clearance that govern drug exposure. In a recent review article, Anderson and Lynn [9] published a search of the literature by using the MEDLINE database regarding age and PK (1979–July 2008) and then evaluated the literature by focusing on drugs with one primary elimination pathway (e.g., renal clearance or clearance involving a single metabolic isozyme). Their analysis revealed that children need weight-corrected doses that are substantially higher than adult doses for drugs that are metabolically eliminated solely by cytochrome P450 (P450) CYP1A2, CYP2C9, or CYP3A4. In contrast, weight-corrected doses for drugs eliminated by renal excretion or metabolism involving CYP2C19, CYP2D6, *N*-acetyltransferase 2 (NAT2), or UGT are similar in children to those in adults. The authors added that in children, bioavailability of drugs with high first-pass metabolism is decreased if CYP1A2, CYP2C9, or CYP3A4 is responsible for the metabolism. However, this report has been contradicted by other reports [157] that indicated for drugs such as voriconazole that metabolized by CYP2C19, CYP3A4, and FMO3 [15] in children required two times as higher bioequivalence dose as those of adults.

16.6 CLINICALLY RELEVANT DRUG INTERACTION IN RELATION TO DRUG METABOLISM IN PEDIATRIC PATIENTS

Metabolism-based DDIs mostly occur when one drug altered the function of DME or enzymes that are responsible for the metabolism and clearance of other drugs, resulting in significant changes in exposure and potential toxicity. A few review articles and clinical studies have recently discussed clinically relevant P450-mediated DDIs in pediatric populations. The medications that are most frequently used and are linked with major interactions in human populations, in adults as well as in pediatric patients, have been illustrated in previous sections of this chapter. Examples of the medications that are known to alter other drug's extent of P450-mediated metabolism in pediatric populations are summarized in Table 16.5. As we outlined previously, drug metabolism can be altered owing to the maturation of body functions, interaction with other medications, genetic variation, diet, etc. This can cause ADRs or DDIs in pediatric populations that are not generally seen in the adult populations. For instance,

1. altered metabolism of sodium valproate in children under three years caused higher incidence of hepatotoxicity;
2. impaired metabolism of chloramphenicol in neonates resulted in the gray baby syndrome (cyanosis and respiratory failure);

TABLE 16.5 P450 Probes in Clinical Studies in Children and Medications That Leads to Potential Drug Interactions

CYP Probe	Substrate(s)	Studies	Modulators of Metabolism	
			Inhibitor	Inducer
1A2	Caffeine	+ Caffeine breath performed in children CYP1A activity detectable in infants >33 days Pons <i>et al.</i> 1988 [36] + Decreased oral caffeine clearance in preterm infants compared with infants and adults Aranda <i>et al.</i> 1979 [18]	Theophylline	Rifampicin Carbamazepine Tobacco Phenytoin
2C9	Diclofenac	+ Systemic weight-corrected Diclofenac clearance increased in children aged four to six years by twofold compared with adults Korpela and Olkkola 1990 [162]	Fluconazole voriconazole	
CYP2C19	Omeprazole	+ Oral clearance increased in children one to six years compared with adults Andersson <i>et al.</i> 2000 [163]	Fluvoxamine	Rifampicin
	Phenytoin	+ Increased clearance in children two to eight years compared with adults Curras <i>et al.</i> 2009 [164]; Yanni <i>et al.</i> 2010 [15]	Fluoxetine	Carbamazepine
2D6	Voriconazole Dextromethorphan	+ Maturation of CYP2D6 pathway ahead of CYP3A4 Johnson <i>et al.</i> 2000 [165]. Phenotype consistent with genotype >14 days postnatal		
	Tramadol, codeine	+ CYP2D6 activity depends on ontogeny, polymorphisms, and renal maturation Allegaert <i>et al.</i> 2008 [67]		
3A	Midazolam (oral and iv)	+ IV clearance, 3–13 years sixfold higher than patients <two year and twofold higher than adults Hughes <i>et al.</i> 1996 [166]	Voriconazole	Rifampicin
	Erythromycin, warfarin	+ Oral clearance, <two years twofold higher than children >12 years Reed <i>et al.</i> 2001 [80]	Itraconazole	Phenobarbital
			Ritonavir	Efaviranez

3. altered drug metabolism caused metabolic acidosis following the use of propofol in the critically ill children; and
4. increased resistance to acetaminophen toxicity in children relative to adults, apparently because of an increased capacity for sulfate conjugation early in life.

In addition to the well-documented cases of drug interactions in pediatric patients that are described previously, there are other studies that reported significant inadequate drug therapy owing to observed metabolism-based drug interactions. For example, Leroy *et al.* [158] reported that intestinal inflammation that compromises CYP3A activities, coadministration with calcium channel blocker and tacrolimus, and genetic polymorphism of CYP3A and (P-gp) resulted in a toxic tacrolimus trough blood level in a renal transplant. In another study with tacrolimus, Moreau *et al.* [167] showed that tacrolimus trough blood concentration increased by introducing omeprazole to liver transplant pediatric patients, although these two drugs are known to be metabolized by different CYP isozymes (the former by CYP3A, while the latter by CYP2C19 and to less extent by CYP3A; Fig. 16.7). The authors concluded that, with a parallel *in vitro* metabolism study with liver microsomes, the interaction between these two drugs is based on competitive (reversible) inhibition of CYP3A-mediated tacrolimus metabolism. When CYP2C19 became saturated in extensive metabolizers (as in this patient) under administration of high dose of omeprazole (or was absent in a poor metabolizer subject), CYP3A becomes a key player in the metabolism of omeprazole and would explain the metabolically based interaction between these two drugs.

One of the therapeutic areas in pediatric patients where the metabolism-mediated drug interaction plays critical roles is the treatment of human immunodeficiency virus (HIV). It requires long-term administration of multiple antiretroviral (ARV) drugs, and usually other medications for possible infections, the occurring illnesses,

Figure 16.7 Effect of omeprazole on tacrolimus blood concentration and serum creatinine in a pediatric liver recipient. Relationship between trough tacrolimus plasma concentration and days of omeprazole administration as well as liver transplantation was presented to determine the interaction between both drugs as shown by the increase in plasma concentration of tacrolimus. The impact of omeprazole interaction on the decrease of serum creatinine was also indicated. Source: Adapted with permission from Moreau *et al.* [167].

or management of side effects. The complexity in this pharmacotherapy indicates that DDIs are inevitable.

Metabolic interactions are a major concern in HIV therapy due to the fact that most PPIs and nonnucleoside reverse transcription inhibitors (NNRTI) are substrate for CYP3A enzymes, which also metabolize 60% of therapeutic drugs [168]. For infants, children, and adolescents, the metabolic capacity of the liver can vary from <10% to >200% of adult values, depending on the age of patients and the enzyme involved [2]. Thus, interactions may be of a greater or lesser magnitude in HIV-infected children.

Ritonavir, for example, inhibits CYP3A in an irreversible, concentration-dependent manner [168]. Ritonavir increases clarithromycin AUC by 77% and almost completely inhibits the major metabolite formation [169]. Ritonavir increased the concentrations of oral and nasal fluticasone, which may result in hypothalamic–pituitary axis suppression [170]. In addition, several reports have indicated that ritonavir inhibits CYP2D6, 2C9, and 2B6, but to a lesser extent than CYP3A4, and has the ability to induce UGT, 2C9, 2C19, 1A2, and 2B6. These effects result in interactions with ethinyl estradiol, voriconazole, and theophylline. Voriconazole AUC is reduced 82% when coadministered with ritonavir [171].

On the other hand, Atazanavir inhibits UGT1A1, which leads to elevations in unconjugated bilirubin in some children, just as it does in adults. This hyperbilirubinemia may be more pronounced in children <18 months as UGT1A1 activity may not have attained adult levels yet [2]. Atazanavir inhibition of UGT1A1 increases raltegravir AUC by 41%, which is a therapeutic interaction. A phase II study observed that more patients achieved low plasma HIV RNA concentrations when received a combination of atazanavir with raltegravir [172] in adults and children.

Interestingly, the AUC of atazanavir is reduced by 74% when given with efavirenz, as this later agent was found to be an inducer of CYP3A4. Higher dose of atazanavir is recommended if combined with efavirenz, although anticonvulsant concentrations must be carefully monitored in children taking efavirenz [173].

On the basis of these information, Fletcher [174] concluded that (linear) extrapolation of the magnitude of DDIs from adults to children is problematic because of the age-associated changes in body composition and organ function. Therapeutic drug monitoring, if available, may be a useful clinical tool to ensure that safe and effective concentrations of antiretrovirals and coadministered medications are achieved.

16.7 LIMITATION IN INVESTIGATING DRUG METABOLISM AND DRUG INTERACTION IN PEDIATRIC PATIENTS: APPROACHES AND EXPERIMENTAL DESIGNS TO OVERCOME SUCH PROBLEMS

The aphorism “Children are not small adults and infants are not small children” applies not only to their anatomy and physiology but also to their drug disposition and drug response. As outlined previously, despite increasing knowledge in ontogeny and drug therapy, there is much to learn about how to determine safe and effective doses of therapeutic agents. Because of perceived ethical considerations, children are rarely included in most product submission studies. Therefore, data on dosing, efficacy, and safety that are available for adults are not usually available for children. When available, data are often not from rigorous clinical trials. Historically, 75% of the drugs have insufficient labeling information for pediatric dosing, safety, or efficacy [175].

Inadequate dosing and safety information places children at risk for adverse events and denies them potential therapeutic benefits.

Several organizations in the United States and Europe have funded research to determine the mechanisms underlying the differences in disposition of drugs between pediatric populations and adults. These efforts aim at determining the role of ontogeny in DMEs and drug transporters with the overarching goal to use this information in setting alternative approaches that predict PK parameters of drugs in children.

Several *in vitro* and clinical studies of probe substrates and drugs used in children and adults have revealed that the ontogeny in DMEs and drug transporters is associated with observed significant differences in PK and safety of drugs between children and adults. Drugs such as omeprazole, theophylline, caffeine, digoxin, cyclosporine, sirolimus, phenytoin, and voriconazole whose clearance is mediated by DMEs (and/or drug transporters) have different plasma clearance in children than in adults. However, to date, knowledge of differences in DMEs and/or transporters between adults and children does not yet allow prediction of the clearance or dose of drugs in pediatric populations based on the adult doses, prospectively. Elucidating the major clearance mechanism(s) of a drug and the differences and/or similarities between children and adults in DMEs, transporters (not addressed in this chapter), and other physiological factors that affect drug disposition using *in vitro* model systems, one can predict clearance, and thus efficacious and safe dose, of the drug in children based on the known clearance and dose in adults. Mechanistic studies should be conducted for all drugs that are currently investigating in children so that our knowledge in drug therapy in pediatric patients is improved and drug safety is ensured. However, because of ethical issues, the availability of biological samples from children to conduct retrospective studies can also be of limitation.

de Wildt *et al.* [176] discussed the challenges encountered when translating adult drug study design to children in clinical practice, using CYP3A phenotyping as an example with probes such as midazolam clearance and erythromycin breath test. Ultimately, the authors were aimed to provide tools that could support pharmacotherapy in pediatrics. As discussed in other sections, the authors have discussed and recommended the use of therapeutic probes; understand the developmental changes in the metabolism pathways and other patients specific covariates; accepting ethical challenges such as limitation of use nontherapeutic probes in phenotyping studies and sampling; considering the use of noninvasive approaches such as urinary drug to metabolite ratio (e.g., hydroxy cortisol/cortisol); and sensitive analytical assay to reduce the sample size. The use of population PK modeling has also proven to be an effective approach to determine drug clearance rate of several drug substrates [81,82,84,132–135,177], can be used to limit sampling per patient, and a means to deal with intersubject variations. Finally, microdosing has been recommended to limit risk of nontherapeutic dose and potential toxicity.

In addition to these review articles, several articles have demonstrated the usefulness of using PBPK models in predicting PK parameters of drug, drug exposure, and safety. The *in vitro* and *in vivo* data are also essential elements in building strategic PBPK; however, there has been great interest in building a pediatric-specific PBPK (P-PBPK) model (Simcyp Pediatric ADME Simulator) by the pharmaceutical industry, regulatory organizations such as the FDA, and clinical practice to improve the efficiency of drug development, especially in populations where designing and conducting clinical studies is more challenging. P-PBPK was used to simulate a number of published clinical

studies. Simulations were used to explore the likely underlying reasons for observed PK behavior of drugs in critically ill children. In addition, the use of P-PBPK models to predict complex DDIs highlighted disparities with adult populations. Prior knowledge of *in vitro* drug provides a starting point to simulate PK and multiple DDI encountered in critically ill pediatric patients [160,161].

In case of nonclinical practice, pediatric tissue banks of normal and diseased specimens should support organizations and academic institutes to conduct molecular mechanistic studies for test drugs; hence, creating a data base for *in silico* prediction of PK and dosing strategy of all drugs will be available before first time dosing in children.

Voriconazole is cleared predominantly by metabolism and *in vitro* studies have implicated CYP2C19, CYP3A4, and in addition to the P450 enzymes, FMO can metabolize voriconazole to its major circulating metabolite, the *N*-oxide [178]. Clinical studies have indicated that voriconazole clearance in children <11 years of age is higher than in adults [179,180] and children have lower oral bioavailability than adults [157]. To elucidate the source(s) of these differences, *in vitro* metabolism studies were conducted using liver tissues from adults and children, and the results were modeled to estimate *in vivo* clearance in children. *In vitro* metabolism of voriconazole by microsomes, prepared from livers of children and adults, showed that the oxidative metabolism is significantly faster in children, as indicated by shorter *in vitro* half-life ($T_{1/2}$). In contrast to similarity in the K_m value, the apparent V_{max} for oxidation of voriconazole to the *N*-oxide is approximately three times higher in children compared with adults. Thus, the microsomal system appears to mimic *in vivo* metabolic clearance of voriconazole. The ratio of Michaelis–Menten kinetic parameters, (V_{max}/K_m) of voriconazole *N*-oxidation by liver microsomes from children and adults, was used to calculate *in vivo* clearance. The calculated scaling factor, based on milligram microsomal protein per gram liver (MPPG) and liver weights that were normalized to BW, was marginally different ($p > 0.04$) between children and adults. The calculated *in vivo* clearance values were ~80% of the observed plasma clearance of voriconazole in children and adults. These results indicate that the higher clearance of voriconazole in children is the result of faster oxidative metabolism by hepatic enzymes. The *N*-oxidation by FMO3 and CYP2C19 in children is five and three times that in adults, respectively, but the estimated rate of *N*-oxidation by CYP3A4 is the same in both groups (Fig. 16.8). On the basis of this study, it has been recommended that prediction of clearance in pediatric population can be based on available PK data in adult populations and comparative data in a relevant *in vitro* assay using tissue from adults and children can be employed to provide an insight for the potential PK in clinic in pediatric patients. Several steps should be considered:

1. The design of *in vitro* studies should be guided by the known mechanism of clearance in adults, such as metabolism, biliary excretion, or renal excretion.
2. *In vitro* clearance of a drug in biological samples from adults to be experimentally determined using *in vitro* concentrations comparable to plasma drug concentrations, then intrinsic clearance to be calculated.
3. The well-stirred model can be used to calculate plasma clearance by including f_u and Q_H values corresponding to age group (Table 16.4a). For neonates, f_u has to be measured in neonatal serum. For older children, f_u were not statistically different than adults [145]; thus, the adult value of f_u can be used for older children.

Figure 16.8 Contribution of oxidative metabolism by P450 and FMO enzymes to the higher voriconazole clearance in children compared with adults. *In vitro* metabolic studies of voriconazole using microsomal samples from children with ages two to eight–years or adults revealed the higher metabolic rate of CYP2C19 and FMO3 enzymes in children, which cause the observed higher clearance in children compared with adults. *Source*: Results adapted from Yanni *et al.* [15].

4. For a metabolically cleared drug, $V_{\max}$ for the formation of major metabolites by pediatric liver samples was determined *in vitro*. Intrinsic clearance in children was calculated by multiplying the ratio of ($V_{\max \text{ child}}/V_{\max \text{ adult}}$) by the ratio of (scaling factor for child/scaling factor for adult).
5. The good relationship of adult *in vitro* intrinsic clearance–*in vivo* clearance will ensure the prediction of the *in vivo* clearance in children based on *in vitro* studies as indicated earlier. Factors that might contribute to the observed disposition of drugs in children might also be revealed from the resulted *in vitro*–*in vivo* relationships.

16.8 OFF-LABEL USE OF DRUG THERAPY IN PEDIATRIC PATIENTS

For a drug to be marketed in the United States or Europe, the maker must submit adequate and well-controlled trials that reveal the efficacy and safety of the product when used as intended to the FDA or European Medicines Agency (EMA). These trials are the basis of the labeling or package insert instructions for approval by the FDA or EMA. Children are usually not included in most product submission studies and, therefore, the data on dosing, efficacy, and safety that are available for adults are not usually available for pediatric patients. Other data may be available but are often not from the same type of rigorous clinical trials. The use of unlicensed and off-label medicines in children is widespread and has raised an increasing concern over the last years. Historically, 50–75% [175,181] of the medicines used in children have only been studied in adults and not necessarily for the same indication [182]. The insufficient labeling information for pediatric dosing, safety, efficacy, and/or appropriate pharmaceutical formulations for use in children may expose them to unwanted overdosing, leading to adverse events or underdosing without the expected efficacy. Lacking such information often denies pediatric patient potential therapeutic benefits. Physicians who care for pediatric populations have, therefore, been forced to either withhold treatment shown to be effective in older patients or provide drugs to children in whom the dose, efficacy, and safety have not been studied. This off-label use of drugs may result in benefit, no effect, or harm, depending on how much other information about the use of the product in the pediatric population is available. The need for more studies to obtain pediatric information for medicines used in children is now a matter of consensus on a global basis [183,184]. The awareness of off-label drug usage in the daily practice by pediatricians and the need to identify specific off-label clinical priorities in pediatrics has been documented.

The Pediatric Research Equity Act of 2003, and very recently draft guidance, has been issued by the FDA with the aim to effectively manage the off-label phenomenon, enabling sponsors to distribute publications about off-label use of approved drugs to prescribers [185]. This has paved the way for the new European legislation (the “Pediatric Regulation”), which was adopted in 2007 with the objective to guide the development and authorization of medicines for use in children aged 0–17 years [186,187]. This legislation was designed to better protect the health of children in Europe. A pediatric committee was established within the EMA with the intent to provide scientific opinions on any development plan for pediatric medicines. The current global discussion of the issues related to pediatric research and regulation [188]

raises a new challenging question: is it always necessary to perform additional clinical studies in children? Studies with Tafuri *et al.* [181], by using available evidence for one of the categories of drugs most frequently used off-label in children: PPIs, showed that, in some instances, the evidence already available may be sufficient to extend the indications to children without further clinical studies. This would allow the translation of the existing evidence into clinical practice, minimizing regulatory hurdles, and avoiding the unethical replication of trials.

16.9 CONCLUSIONS

We have provided a summary of the current state of knowledge on drug metabolism in pediatric populations and interactions that could arise owing to the maturation of DME activities; other physiological parameters that have impact on drug metabolism; and/or from the effect of comedication, disease state, genetic factors, or diet. Furthermore, this chapter has provided an overview on how the differences in drug metabolism in children relative to adults and the resulting effects on the PK and pharmacodynamics of drug therapy, specifically safety and efficacy. It is anticipated that while there are several ethical issues that hinder further translational research and clinical studies in pediatric patients, the recommendations and knowledge included in this chapter can aid other scientists and clinician with their investigations, support the design of future clinical studies, and hopefully reduced off-label use of drugs in neonates and children.

17.1 SUMMARY

Simulating and predicting interindividual variability in drug pharmacokinetics (PK) and drug–drug interactions has become an integral part of drug development and clinical therapeutics. Our understanding of the mechanisms by which anatomical, physiological, or genetic differences translate into variability is quite advanced and even, to a large extent, quantitative. PK modeling is a mature field where compartmental models and, in particular, physiologically based pharmacokinetic (PBPK) models have been used since the 1970s. PBPK models differ from empirical compartmental models, in that they describe well-identified tissues or organs, linked at least by blood flow. With the help of such models, variability can be studied either *a priori*, through purely predictive computer simulations, or *a posteriori* to discover the determinants of variability through data analysis. Predictive simulations rely on the continued development of detailed organ simulation models and QSAR/QSPR (quantitative structure–activity relationship/quantitative structure–property relationship) models, which are able to finely describe the processes of drug absorption, excretion, or metabolism at specific sites of the body. To be able to forecast the existence of sensitive subpopulations, they require the data mining of parameter values for these processes in large populations,

or at least in subpopulations, differing in sex, age, ethnicity, disease state, and so on. The development of *a posteriori* population PK analyses followed the diffusion of specialized (multilevel) statistical models able to disentangle variability from uncertainty, which is always present in clinical study data. Improved numerical techniques, such as the Bayesian Markov chain Monte Carlo (MCMC) methods, are now bridging the gap between the *a priori* and the *a posteriori* approaches, using them in a refining cycle of model calibration and model prediction. These techniques have been successfully applied to complex PBPK models. The future should see ever improving PBPK models, linked to organ physiology models and cellular effect models. We are progressing toward the development of predictive PK and pharmacodynamic analyses of drug safety and efficacy with ever finer descriptions of individual susceptibility. This drive is congruent with the current development of personalized medicine.

17.2 INTRODUCTION

Inter- or intraindividual variability in drug PK, and particularly in metabolism, translates into variability of target doses. Such variability can have direct consequences for therapeutic safety and the likelihood of toxicity, especially for compounds with narrow therapeutic windows. Therefore, understanding, simulating, and predicting interindividual variability have become an integral part of the assessment of PK in humans [1]. The mechanistic framework of mathematical PK models, and in particular PBPK models, provides the capacity to predict drug–drug interactions and interindividual variability in PK when the required information is adequately incorporated [2–5]. This chapter presents the state of the art on that question, reviewing the deterministic (mechanism-based) and stochastic (statistical) methods currently available. The corresponding pharmacodynamic aspects are not reviewed here. Those are largely beyond the scope of metabolism studies and models.

17.3 APPROACHES TO MODELING DRUG METABOLISM AND INTERACTIONS

Interindividual differences (variability), in the anatomical and physiological characteristics of humans or animals are a glaring and a common experience. Such differences affect, for example, metabolic clearance, organ volumes, and blood flow and translate quite naturally into variability in the PK of drugs and chemical substances from one individual to the next. Since PK determine, in part, effective dose and ensuing effects, PK variability has an impact on individual susceptibility. Two complementary modeling approaches have been developed to understand, evaluate, and predict that variability: *a priori* and *a posteriori* modeling.

A priori predictive variability modeling can be undertaken through deterministic descriptions of the determinants of variability or through stochastic simulations (Monte Carlo methods) [1,6–10]. Both approaches can also be combined. Deterministic modeling is made possible by the fact that some of the differences between individuals are known to be due to age-related changes, genetic makeup, sex, and so on. Such changes can be explicitly modeled in lifetime PBPK models, for example [4,11]. Monte Carlo methods, on the other hand, acknowledge the fact that part of the differences between

individuals seem to occur by chance or cannot be ascribed to obvious causal determinants. Such differences are then considered as random and the corresponding parameter values are described by statistical distributions, rather than by point estimates or simple functions of time, age, and other covariates.

A posteriori modeling of interindividual variability is data based and was originally developed in PK, where human data are routinely generated through clinical trials. The aim here is to assess, for example, whether the across-subject variability of blood concentrations for a given drug can be explained by variability in bioavailability, metabolic rate, and so on. And this is best achieved through model calibration (data fitting) in the framework of a multilevel statistical model: in our case, a “population pharmacokinetic model” [12]. The population approach was first used with classical (minimal) compartmental models [13], but the added ingredients of MCMC simulations and Bayesian inference made it amenable to the treatment of PBPK models [14]. After identifying the determinants of variability, predictive simulations can be performed to assess their impact in various therapeutic treatment scenarios.

Uncertainty is different from variability, although their effects may be both confounded and compounded. Uncertainty is primarily due to imperfect knowledge and may have various sources. For example, studying a limited number of patients introduces an element of randomness when attempting to extrapolate the results to the whole population. Also, measurements are made only with finite precision, so when data are used to fit PK or pharmacodynamic models, there is always some residual uncertainty about the estimated parameter values (including the values of parameters measuring variability). Finally, our inability to model a biological system in all its details may result from lack of understanding, simplifications, or misspecifications. This translates into parametric uncertainty for the fitted models [2,15].

While variability is irreducible and unavoidable, as it is a state of Nature, uncertainty can be reduced by new experiments or clinical trials or by a better understanding of the biology and improved models of it. Statistical population models are able to account separately for variability and uncertainty and can help disentangle the two. These models are reviewed in this chapter (Section 17.5).

17.4 A PRIORI PREDICTION OF VARIABILITY THROUGH PBPK MODELING

17.4.1 PBPK Modeling

When a chemical substance penetrates an animal body (following intentional administration or unintentional exposure), it is usually distributed to various tissues and organs by blood flow [16]. Following its distribution to tissues, the substance can bind to various proteins and receptors, undergo metabolism, or can be eliminated unchanged. The concentration versus time profiles of the xenobiotic in different tissues, or the amount of metabolites formed, are often used as surrogate markers of internal dose or biological activity [17].

Mathematical models can be used to interpolate and extrapolate (predict) such concentration–time profiles from data. Reported models range from simple compartmental [18] to very sophisticated ones [4]. PBPK models are evolved compartmental models that try to use realistic biological descriptions of the determinants of drug disposition in the body [19]. Those models describe the body as a set of compartments

Figure 17.1 Schematic representation of a PBPK model for the model and fetus. The various organs or tissues are linked by blood flow. The parameters involved are compartment volumes, blood perfusion flow, tissue affinity constants (or partition coefficients), and specific absorption, diffusion, metabolic, and excretion rate constants.

corresponding to specific organs or tissues (e.g., adipose, bone, brain, gut, heart, kidney, liver, lung, muscle, skin, and spleen) (Fig. 17.1). Between compartments, the transport of substances is dictated by various physiological flows (blood, bile, pulmonary ventilation, etc.) or by diffusions [20,21]. Perfusion-rate-limited kinetics applies when the tissue membrane presents no barrier to distribution. Generally, this condition is likely to be met by small lipophilic substances. In contrast, permeability-rate kinetics applies when the distribution of the substance to a tissue is rate limited by the drug's permeability across the tissue membrane. This condition is more common with polar compounds and large molecular structures. Consequently, PBPK models may exhibit different degrees of complexity. In the simplest and most commonly applied form (Fig. 17.1), each tissue is considered to be a well-stirred compartment, in which the substance distribution is simply limited by blood flow. In such a model, any of the tissues can be a site of elimination. However, in Fig. 17.1, it is assumed that the gut, liver, and kidney are the only metabolizing tissues and that excretion only happens in the kidney.

Building a PBPK model requires gathering a considerable amount of data which can be categorized in three groups, namely, systemic data (physiological, anatomical, biochemical data), drug-specific data, and the model structure, which refers to the arrangement of tissues and organs included in the model [22]. In a sense, PBPK

modeling is an integrated systems approach to both understanding the PK behavior of compounds and predicting concentration–time profiles in plasma and tissues. Additional details on PBPK modeling can be found in Refs. 20 and 22–25 and in the volume titled *ADME of Drugs*, part titled *General Principles of ADME. Drug Transporters and Other Mechanisms of Transport* of this encyclopedia. Indeed, such descriptions of the body are approximate, if not rough, but a balance has to be found between precision (which implies complexity) and simplicity (for ease of use). Yet, the generic structure of a PBPK model facilitates its application to any mammalian species as long as the related system data are used. Therefore, the same structural model can approximately be used for a human, a rat, or a mouse [26].

17.4.2 Monte Carlo Methods

Predictive variability assessment with PBPK models proceeds currently with a combination of mechanism- and data-based refinements of the model structure (e.g., using age-dependent compartment volumes) [27] and stochastic modeling of the remaining random components of interindividual differences. Numerical Monte Carlo methods [28], eventually with hierarchical sampling [29], are the most widely used for the latter task. Those are best suited for complex models with many parameters. The basic assumption made by Monte Carlo simulations is that the randomness of the model state variables (e.g., blood concentration) is simply due to the randomness in the model parameter values. It is enough then to define statistical distributions for the parameters supposed to vary randomly in the population and to sample the model parameter values from those distributions. The model is then run with the needed inputs, and its outputs of interest are recorded (Fig. 17.2). That sampling-running step constitutes a basic Monte Carlo iteration. As many iterations as needed can be performed to characterize precisely the statistical distribution of the recorded outputs. Additional details of Monte Carlo methods can be found in Ref. 30.

Early attempts to use Monte Carlo methods and to simulate PK behavior in “virtual populations” date back to the mid-1980s. Jackson *et al.* [31,32] assessed the robustness of different experimental *in vivo* indices to detect and display genetic polymorphisms in human drug–metabolizing activity. Monte Carlo analyses of PBPK models were also described at that time [7,33]. These simulations were later expanded to show the effect of variability in absorption, distribution, metabolism, and excretion (ADME) parameters on the power of single time point estimates for the assessment of metabolic activity [34], the differentiation of parent drug and metabolite data in bioequivalence assessment [35], the discriminatory power of different indices of *in vivo* enzyme activity, and the optimization of sampling to assess such activity [36]. Coupled with Monte Carlo methods, PBPK modeling has been used to assess the quantitative impact of physiological and environmental factors on human variability in toxicokinetics and PK in other publications [4,6,37–39].

17.4.3 Sources of Variability in Pharmacokinetics

The overall interindividual variability in PK can be simulated by considering the variability in key system parameters in PBPK modeling[4]. Details on the prediction of interindividual variability in PK are briefly reviewed below.

Figure 17.2 Application of Monte Carlo simulations to a PBPK model. Three steps are iterated a large number of times. Step 1: parameter values are randomly sampled out of specified statistical distribution functions. Step 2: the PBPK model is run for a particular exposure and observation scenario using the sampled parameter values. Step 3: the outputs of the PBPK model (e.g., the liver concentration at various times) are collected. Those outputs can be further analyzed for uncertainty or sensitivity analysis.

17.4.3.1 Absorption. Oral, infusion, intravenous, intramuscular, transdermal, and inhalation routes are routinely used for drug administration. Among them, the oral, transdermal, and inhalation routes are the most affected by variability.

17.4.3.1.1 Oral Absorption. Oral administration is the most common and convenient route of drug administration. Yet, it is often associated with low bioavailability and high interindividual variability. After oral administration, the drug is first released from formulation, then gets dissolved in the gastrointestinal fluid, and passes sequentially through the intestinal wall and the liver, before entering the systemic circulation. Oral bioavailability, F_{oral} , is usually defined as

$$F_{\text{oral}} = f_a \cdot F_G \cdot F_H \quad (17.1)$$

where f_a is the net fraction of dose absorbed from the intestinal tract, F_G is the fraction of dose that escapes intestinal first-pass metabolism in the enterocytes, and F_H is the fraction of dose that escapes hepatic first-pass metabolism.

The majority of drug absorption occurs in the small intestine because of its large absorptive surface area and high blood perfusion rate. The large intestine has a considerably smaller absorptive surface area than the small intestine, but it may still serve as a site of drug absorption for compounds that are not completely absorbed from the small intestine. Drug-related factors affect oral drug absorption, but physiological and biological factors, such as gastric emptying time, intestinal residence time, or regional pH in the gastrointestinal tract, mostly affect variability.

Gastric emptying strongly conditions the residence time of a drug in the stomach. It is an important factor for the initiation of oral drug absorption. Variability in gastric emptying rates results usually in variable absorption rates and sometimes even variable absorption extents. The rate of gastric emptying is influenced by both volume and composition of gastric contents. Additional factors influence the residence time of a drug in the stomach, including the nature of the dosage form, the volume of water coadministered, and presence of food [40]. Generally, the process of gastric emptying is modeled as a first-order process; however, it is in fact very complex.

Intestinal residence time can greatly affect oral drug absorption, particularly for drugs with low permeability. Yu and coworkers [41] analyzed published data for small intestinal residence time in over 400 subjects and reported a mean value of 199 min with ranges of about 1 and 6 h. Intestinal residence time appears to depend somewhat less on the dosage form (liquid vs solid) than on the gastric residence time [42]. The presence of food does not appear to influence intestinal transit [42,43].

The regional pH in the gastrointestinal tract can influence drug solubility and hence the dissolution of solid dosage forms. Gastrointestinal pH may also affect drug permeability by influencing the balance between ionized and nonionized moieties. Fallingborg and coworkers [44] measured pH profiles along the gastrointestinal tract in 39 healthy volunteers and observed pH values ranging up to two units at the same site in different subjects. In addition, the presence of food in the gastrointestinal tract can raise the pH in stomach and the proximal part of the small intestine because of the buffering capacity of proteins. Following a meal, gastric pH gradually returns to its basal value (corresponding to the fasted state) [45]. The return rate is considerably slower in elderly subjects than in young subjects [46]. Gastrointestinal pH is also affected by other factors including pathological states such as achlorhydria and hypergastrinemia [47].

In addition, various transporters are variably expressed in the apical and basolateral membranes of intestinal epithelial cells [48–52]. Much attention has been given to the efflux transporters (e.g., P-gp, MRP2, and BCRP) at the apical (brush border) membrane of the intestine, as they can limit the intestinal absorption of drugs administered orally [53–55]. Available data demonstrate that the expression levels of transporters vary along the gastrointestinal tract; for example, the relative P-gp levels increased progressively from the proximal to distal region [55]. Little is known about the pattern followed by other intestinal transporters.

Key physiochemical properties, such as solubility and permeability, can be used in empirical methods to estimate the absorption potential of a drug [56,57]. But physiological models, such as the Compartmental Absorption and Transit (CAT) model [58], have also been developed to mechanistically simulate drug absorption. The CAT

model has been further developed into the Advanced Compartmental Absorption and Transit (ACAT) model [59] and the Advanced Dissolution, Absorption, and Metabolism (ADAM) model [60], which are implemented within software GastroPlus (Simulation Plus Inc, California, USA, www.simulationsplus.com) and Simcyp Population-based ADME Simulator (Simcyp Ltd, Sheffield, UK, <http://www.simcyp.com>), respectively. In brief, these absorption models consist of physiologically based compartments corresponding to different segments of the gastrointestinal tract. A series of differential equations are used to describe drug release, dissolution, degradation, metabolism, and absorption within each segment and drug transit from one segment to the next. For each drug phase in the small intestine, for example, solid and dissolved drug, a segment is modeled as a well-stirred compartment in which different processes such as dissolution/precipitation, absorption/efflux/uptake, and transit can simultaneously happen.

17.4.3.1.2 Inhalation. The large absorptive surface area, limited metabolic enzyme activity, and active transporters in the pulmonary system make inhalation a favorable delivery strategy for systemic drugs with low bioavailability. As for other routes of administration, the absorption kinetics in the lung tissues depend on both drug- and system-related parameters. Different aspects of lung physiology and formulation composition that influence the systemic delivery of inhaled therapeutics and recent advances in inhaled drug delivery have been reviewed previously [61].

17.4.3.1.3 Dermal Absorption. The skin is the largest interface between the environment and the body and protects the body against chemical, physical, and microbial injury; loss of water; and other endogenous substances. It is involved in thermoregulation and assumes excretory functions [62]. Permeation of drug molecules across the skin occurs by passive diffusion according to the chemical activity gradient [63–65]. The outer skin layer, stratum corneum, forms a rate-controlling barrier for diffusion of most compounds. The predominant diffusional path for a molecule crossing the stratum corneum appears to be intercellular [66]. However, this path is not exclusive, and probably, most molecules pass through the stratum corneum by a combination of routes [67,68].

17.4.3.2 Distribution. Distribution here refers to the reversible transfer of drug from one location to another within the body. The processes that determine the transport of drugs in the body include their delivery to tissues by blood flow or lymphatic circulation and their ability to cross membranes, bind to proteins within blood and tissues, partition into fat, and to be subject to active uptake in tissues [69]. Those processes depend on drug-specific factors such as ionization, lipophilicity, and binding affinity to plasma proteins or influx or efflux transporter proteins. But drug distribution is also affected by physiological factors such as tissue volumes, perfusion and composition, plasma protein concentrations, hematocrit, and the expression of transporter proteins, which we briefly review here.

17.4.3.2.1 Tissue Volumes and Blood Perfusion. Tissue volumes and tissue blood flows are essential components of a PBPK model, but early systematic publications reporting physiological parameter values did not indicate the biological variability associated with those data [70,71]. Interindividual variability on those parameters has since been reviewed [72,73]. The correlation between tissue volume and perfusion

should be considered when modeling interindividual in PBPK models, because it is blood perfusion rate per unit tissue mass that is actually maintained by homeostasis [71]. Drugs can be distributed between plasma and red blood cells, and hematocrit, the percentage of total blood volume occupied by red blood cells, is influenced by factors including age, sex, seasonal influence, and habits of physical activity [74–76]. Hematocrit ranges between 40% and 54% in males and 38% and 47% in females. For drugs that get heavily distributed into the red blood cells, such as cyclosporine, hematocrit variation can affect the drug clearance [77].

17.4.3.2.2 Tissue Composition. For drugs effectively transported by blood, the tissue-to-plasma partition coefficients (K_{tp}) can be used to characterize their affinity for the various tissues of the body. These coefficients are the ratios of tissue concentration over plasma concentration in steady-state conditions. They are determined by the drug partitioning between lipids and water, as well as by their binding to common proteins present in the tissue interstitial space. Most of the studies on tissue composition (water, neutral lipids, phospholipids, etc.) were carried out between the late 1960s and the mid-1980s [78–81], and overall, data on human tissue composition and related variability are very limited.

17.4.3.2.3 Drug-Protein Binding. This is a reversible interaction of drugs with plasma proteins and is a function of drug and protein concentrations, the affinity constant for the drug-protein binding, and the number of protein binding sites [82]. The major drug-binding proteins in plasma are albumin, α_1 -acid glycoprotein (AAG), and lipoproteins. Albumin levels generally decrease with age, whereas AAG levels are not significantly affected by age. Many pathophysiological, pharmacological, and environmental factors, such as renal disease, hepatic disease, obesity, trauma, stress, surgery, pregnancy, concomitant drug therapy, or smoking, can alter the concentration of albumin and/or AAG.

17.4.3.2.4 Transporters. Numerous drug transporters are found in tissues membranes. These transporters can influence drug distribution into the tissues, particularly for drugs with low passive permeability [83]. For most drugs, transporters may influence the local kinetics in certain tissues (e.g., brain, liver), with pharmacological and toxicological consequences. Polymorphism is present in transporters, as reviewed, for example, by Ho and Kim [84].

17.4.3.2.5 Prediction of Drug Distribution. As discussed above, PBPK models provide a mechanistic and reasonably realistic description of the behavior of a substance in the body. They also give access to predictions of interindividual variability in drug distribution, through Monte Carlo simulations. Moreover, the development of mechanistic methods for predicting tissue-to-plasma partition coefficient, K_{tp} , values have greatly extended the application of PBPK modeling in drug discovery. K_{tp} values are important parameters in PBPK models. Their direct determination is costly and time consuming, as it usually involves intravenous constant infusion to animals followed by an extraction and quantification of the drug from tissue homogenates [85–87]. It is therefore of interest to estimate K_{tp} values without conducting *in vivo* animal studies. Several mechanistic equations (in essence, these are QSPRs) have been proposed to predict the tissue affinities of volatile organic compounds [88–90] or drugs [91–94].

The mechanistic basis of these parametric equations is that each tissue and plasma is a mixture of lipids, water, and plasma proteins. The assumptions are that the drug distributes homogeneously into each tissue and plasma by passive diffusion, partitions between lipids and water, and binds reversibly to common proteins present in plasma and tissue interstitial space. Values for the main compound-specific parameter of these equations can be provided by *in vitro* data on the drug lipophilicity and plasma protein binding. The species-specific tissue composition parameters can be found in the literature [95]. These equations have been extended and improved by considering drug ionization and incorporating more details on drug distribution inside tissues. Briefly, the assumptions are that all drugs will dissolve in intra- and extracellular tissue water and partition into the neutral lipids and neutral phospholipids located within cells. Compounds with at least one $pK_a \geq 7$ (ionized bases and corresponding zwitterions) are assumed to have electrostatic interactions with tissue acidic phospholipids. These compounds tend to preferentially bind to AAG. Since AAG is largely restricted to plasma, its interaction with extracellular proteins can be considered to be minimal. For other compounds, associations with extracellular proteins are an essential component, with acids and weakly basic compounds being assumed to bind primarily to albumin and neutral ones to lipoproteins [96,97]. As mentioned earlier, drug distribution into a tissue can be rate limited by either blood perfusion or membrane permeability. In the first case, the tissue can be regarded as a well-stirred system and the above calculations of partition coefficients apply. In the second case, a more realistic yet more complex model is needed and tissues need to be divided into two or more compartments to represent vascular blood, extracellular space, and intracellular space separated by permeability barriers [20,98].

17.4.3.3 Metabolism. Drug metabolism is the major mechanism for elimination of most drugs and its reactions are generally grouped into two phases. Phase I metabolism includes oxidation, reduction, hydrolysis, and hydration reactions. Phase II reactions use an endogenous compound, such as glucuronic acid, glutathione, or sulfate, for conjugation to the drug or its phase I-derived metabolite to produce more polar end products that can be more readily excreted in bile or urine. Although drug metabolism can take place in many organs, the liver has been long recognized as the major site of metabolism for most drugs. The role of gut metabolism in first-pass metabolism is also well recognized, the intestinal tissue being endowed with phase I and II enzymes, although at lower levels than those for the liver [99].

17.4.3.3.1 Hepatic Metabolism. Rane *et al.* [100] successfully predicted *in vivo* hepatic metabolic clearance in rats based on *in vitro* data obtained from rat liver microsomes, taking into consideration the hepatic blood flow rate and the unbound fraction in blood. Since then, significant progresses have been achieved on predicting human hepatic metabolic clearance from a variety of *in vitro* systems, such as human liver microsomes, recombinant enzymes, and hepatocytes [101–108].

Interindividual variability in the hepatic metabolic clearance of a drug is mainly determined by the variability of three key parameters: hepatic blood flow, the free (i.e., unbound to proteins or hepatocytes) fraction of the drug in blood, and most importantly, enzyme abundances in the liver. When drug distribution into the liver is permeability limited, variability in hepatic transporters also plays a role. Hepatic blood flow is the sum of hepatic arterial and hepatic portal vein blood flows, representing about 6.5%

and 19% of cardiac output in male adults, respectively, and 6.5% and 20.5% of cardiac output in female adults, respectively [109]. Cardiac output is dependent on body surface area as well as age [110,111]. The free fraction of the drug in blood is determined by variations in drug-binding protein concentration and hematocrit. Interindividual differences in the expressions and catalytic activities of various drug-metabolizing enzymes are often the major causes of the large interindividual variability observed *in vivo* in drug metabolism. In humans, about 15 different CYPs have been identified as being involved in drug metabolism in the liver. These P450s have been characterized to varying degrees with respect to their regulation of expression and catalytic activities [112]. Meta-analyses of data on CYP abundances in liver and their variances have been performed for Caucasians [113] as well as for Japanese and Chinese [114]. The abundances of UDP-glucuronosyltransferases (UGTs) in the human liver and their interindividual variability have also been reported [115]. Differences in metabolism that result from functional genetic polymorphisms can be inferred from the frequency of the different genotypes. PK differences between phenotypes are most relevant for drugs with low therapeutic indices. Inherited defects in several drug-metabolizing enzymes such as CYP2D6, CYP2C19, and CYP2C9 have long been recognized to be critical to the observed therapeutic efficacy or toxicity of certain drugs. It is also known that the content and activity of CYP enzymes can decline in patients with liver diseases [116].

Several models have been developed to quantify the effects of varying hepatic blood flow, fraction unbound in blood, and hepatic enzyme activities on hepatic clearance [117]. Among those, the well-stirred model has been widely used for its mathematical simplicity and practicality. The well-stirred model first assumes that drug distribution into the liver is perfusion limited with no diffusion delay and that no active transport systems are involved. It also assumes that the drug is distributed instantly and homogeneously throughout liver water and that the unbound drug concentrations in plasma and liver water are identical. When enzyme activities are measured using recombinantly expressed enzyme, human liver microsomes, or human hepatocytes, they are usually normalized using the amount of microsomal protein per gram of liver (MPPGL) or hepatocellularity (the number of hepatocytes per gram of liver (HPGL)). In that case, the variability of these normalizing factors and that of liver mass has also an impact on the model predictions. The 95% confidence interval of the geometric mean ranges from 27 to 32 mg/g for MPPGL and from 74 to 131×10^6 cells/g for HPGL [108]. A modest decrease in MPPGL with age was also reported. For liver mass, a predictive model based on body surface area and ethnic differences, based on data from more than 5000 individuals aged from birth to 28 years, is available [118,119].

17.4.3.3.2 Gut Metabolism. Several CYP enzymes (CYP1A2, CYP2D6, CYP2E1, CYP2C8, CYP2C9, CYP2C19, CYP3A4, and CYP3A5) have been evidenced in the human small intestine, CYP3A4 being the most prominent [120,121]. Although the total content of CYP3A in the entire human small intestine is only 1% of that in the liver [121,122], the fraction of CYP3A substrates processed in the intestine is often similar to or even exceeds the fraction processed in the liver [123].

The determinants of interindividual variability in intestinal metabolism include mainly the blood flow to the small intestine, enzyme abundances in the gut wall, effective intestinal permeability, and intestinal cylindrical surface area [124]. The blood supply to the small intestine is provided by the superior mesenteric artery and constitutes about 10% of the cardiac output in an average adult [109]. In the unfed state,

mucosal blood flow represents about 80% of the total mesenteric flow, and in turn, about 60% of mucosal blood flow supplies the epithelial cells of the intestinal villi [125]. Hence, villous blood flow is about 4.8% of the cardiac output [124]. Following a meal, blood flow increase can be as high as 200% above baseline levels and persists for 2–3 h [125]. The total CYP3A content of microsomes prepared from mucosal scrapings of the duodenal and jejunal portion of 31 human donors averaged 50 pmol/mg and ranged from 18 to 151 pmol/mg [120]. Along with CYP3A4, CYP2C9 and CYP2C19 were detected in all donor intestines and their concentrations varied at least fivefold between individuals. Effective intestinal permeability (per unit surface area) is related to drug permeability but can be affected by the abundances of intestinal transporters and pH in the gut lumen. Intestinal cylindrical surface area is also variable among individuals.

A “ Q_{Gut} ” model has been developed to predict first-pass metabolism in the gut [124,126,127]. This model retains the form of the “well-stirred” model but is an empirical model rather than a fully physiological model such as the ADAM model.

17.4.3.4 Excretion. Excretion is usually defined as the irreversible loss of the chemically unchanged drug. For most drugs, excretion occurs predominantly via the kidneys. However, some drugs and their metabolites are extensively excreted in the bile. Drug excretion can also happen via saliva, sweat, breast milk, and lungs, although their contributions to overall drug elimination are often small.

17.4.3.4.1 Renal Excretion. The kidney is the major site of drug excretion. Net renal drug excretion is a combination of three processes: glomerular filtration, tubular secretion, and tubular reabsorption. The glomerular filtration of a drug is a passive process that is dependent on the unbound fraction of a drug in plasma (f_u) and renal blood flow available for filtration. Tubular secretion occurs predominantly in the proximal tubule and is mediated by several families of transporters, including the organic anion transporters (OATs) and organic cation transporters (OCTs). Tubular reabsorption can be a passive or an active transport process. Active reabsorption occurs in the proximal tubule and, similar to tubular secretion, is energy dependent, saturable, stereospecific, and likely to be associated with competitive drug interactions [128]. Active transports are mediated by several families of transporters, which play key roles in the secretion and reabsorption of many drugs. Passive reabsorption may occur throughout the nephron. It is largely due to the reabsorption of water, which concentrates the urine with respect to plasma.

The primary determinants of renal excretion are renal blood flow, plasma protein binding, urine flow, urine pH, and activity of renal transporters [129,130]. The extent of sensitivity to these parameters depends on the nature of the compound considered and the mechanisms involved in its renal elimination (e.g., glomerular filtration, active secretion, passive reabsorption). Thus, interindividual variation in these parameters determines the renal clearance. Urine flow is sensitive to individual fluid intake and administration of diuretic drugs. Urine pH can affect the ionization degrees of low molecular weight weak acids and weak bases and therefore influence their reabsorption. Nonionized drugs are usually lipophilic and are therefore likely to be reabsorbed through tubule back into the circulation [131]. Interindividual differences in urine pH are mainly related to differences in diet and physical activity [132]. Renal transporters play key roles in the secretion and reabsorption of many drugs and can significantly

contribute to the variability in renal excretion of these compounds [133]. Organic anion and organic cation transport systems are two major drug transport systems in the human kidney [134], and the effects of genetic variations in transporters on renal clearance have been investigated recently [135]. A range of pathophysiological states also influence the efficiency of individual renal elimination pathways [128,130]. It is well recognized that renal diseases alter the renal clearance and therefore the elimination of drugs. Although it is obvious that renal impairment is associated with a decrease in renal excretion of a drug and its metabolites, renal impairment has also been shown to be associated with other changes in absorption, hepatic metabolism, plasma protein binding, and drug active transport [136]. The underlying mechanisms of these effects are not yet fully understood in humans.

Current *in vitro* models to investigate the complex parallel processes for renal clearance are limited, and the prediction of renal clearance of drugs in humans is usually based on preclinical animal data.

17.4.3.4.2 Biliary Excretion. Biliary excretion is one of the primary elimination routes for xenobiotics and their conjugate metabolites [137]. Biliary excretion requires active secretory transport since drugs are transported across the biliary epithelium against a concentration gradient. Drugs excreted into the bile often undergo some degree of reabsorption along the intestine (enterohepatic circulation). If the biliary excreted drug is totally reabsorbed from the intestine, biliary secretion is a component of drug distribution. Only when there is no or incomplete reabsorption from the intestine does it become a route of elimination.

Biliary excretion is mediated by transporters in the canalicular membrane. Therefore, genetic variation in these transporters contributes to the interindividual variability in biliary excretion [138,139].

Biliary excretion of drugs can be investigated using *in vitro* systems with varying degrees of complexity spanning from the whole hepatocyte to membrane vesicles prepared from cell lines transfected with specific transport proteins [139]. Nevertheless, the predictive accuracy of these methods in humans is largely unknown owing to the lack of clinical data on the biliary excretion of drugs. *In vitro* data obtained from sandwich-cultured human hepatocytes to predict the biliary clearance for three drugs, significantly underestimated values obtained *in vivo* [140].

17.4.3.5 Drug–Drug Interactions and Coexposures. Part of the large variability in metabolism observed in humans may also be due to uncontrolled coexposures to naturally occurring food-borne substances, environmental contaminants, therapeutic drugs, or chemical substances in the workplace. Drug–drug interactions are a well-known problem falling under that umbrella [1,4,141], but its generalization to many-substance exposure remains to be better explored, even though the necessary tools are becoming available [5,142,143].

The challenge is to efficiently describe together cascades of reactions and the eventual transport and elimination of intermediate and final metabolites. The associated model can be very complex, even if limited to PK and metabolic interactions because the transport of each metabolite requires a set of differential equation of its own. Generic PBPK modeling for absorption, distribution, and excretion, coupled to a systems biology approach (able by design to deal with a large number of interacting

substances), for metabolism appears to be a promising way toward the solution of that question [144].

17.5 A *POSTERIORI* ESTIMATION OF VARIABILITY USING POPULATION MODELING

17.5.1 Motivation

Purely predictive modeling, as described above, can be cross-validated by confronting its predictions (e.g., for plasma concentration of a substance) to data obtained of a sample of individuals. In the ideal case, data and predictions agree both on average and in terms of variability and no further model refinement is attempted. But quite often, the predictions are less than “perfect” and may even be really poor (even though publication bias reduces the visibility of that case). That may be the occasion to improve the model through some calibration or data integration procedure and learn something about the true determinants of variability in a population [145]. However, some care should be taken to properly disentangle uncertainty from variability in that calibration process. In addition, when a PBPK model is examined in that context, it is important to retain the prior physiological knowledge it embodies in its parameter definition and values [14]. The “naive” approach consists in fitting individual subjects’ data separately, collecting the resulting individual parameter estimates, forming their average, and so on. That approach does not work and is actually incorrect if very precise parameter estimates cannot be obtained from the data [13,146]. For ethical, feasibility, or cost reasons, the data on individuals tend to be sparse in clinical PK or toxicokinetics. Such data usually lead to fairly uncertain parameter estimates and the so-called population approaches should then be used [147].

We review in the following section the typical PK data available for calibration, the general structure of population models, and the tools available to actually perform statistical inference using those models. As to actual applications, published population PK analyses are too numerous to be usefully surveyed here. Note that useful extensions to clinical trial optimal design [148–150], including for drug–drug interactions [151,152], have been proposed. In addition, pharmacodynamic drug interactions can also be studied with these methods [153–155].

17.5.2 Typical Population Pharmacokinetic Data

An example of population-based PK data is given in Fig. 17.3. Caffeine blood concentration was measured (for therapeutic monitoring) at one to four time points in 35 premature newborns. Measurements followed intravenous injection at various recorded times. Typical for a population data set, the data are sparse, most subjects having only one or two measurements. In such a fragile population, frequent blood sampling is counterindicated. Little could be drawn from such data if caffeine kinetics were not relatively simple (caffeine distributes uniformly in body water). In addition, body mass, a covariate measurement of body water content, was daily measured during all treatment. Taken together, blood data, covariates, and a PK model were able to predict individual and population caffeine kinetics for improved treatment and monitoring [156].

Figure 17.3 Example of population pharmacokinetic data. Caffeine concentration in venous blood was measured in 35 premature newborns at one or several times. Linked points belong to the same subject. *Source:* adapted from Ref. 156.

17.5.3 Statistical Population Models for Clinical Trials

Population models, or multilevel models, were first introduced in the context of PK studies for drug development and evaluation [157,158]. Their objective is to obtain, from data on individuals, a quantitative description of the variability of the kinetics of a compound within a large population. The same structural PK model is used to describe the data for each subject, and the model parameters are assumed to differ randomly between subjects (Fig. 17.4) [159–161].

The structural model can be of any complexity as desired, from the basic one-compartment model to a full-fledged lifetime PBPK model. The scope of population models is actually not limited to PK. Pharmacodynamic data, for example, may be analyzed with the same tools [158,162–164]. The randomness between subjects characterizes variability and can be described by a multivariate probability distribution if several parameters are supposed to vary at once, as it is often the case. In population models, information of each subject is reinforced by “borrowing strength” from the other subjects’ data and the overall estimation process is improved. Individuals’ metabolic clearance, for example, can be assumed to be lognormally distributed around a “population mean,” with a “population variance” that measures variability in the population. The population means and variances (one for each kinetic parameter supposed to vary between subjects) form the “population” parameters. They are estimated during the model calibration (data fitting) together with the parameters of each subject [2,13,165]. Other population parameters can be defined, such as parameter covariance (if some parameters are supposed to be correlated at the population level) or degrees of freedom (if a (Student) t -distribution is assumed instead of the normal distribution) [161].

For a typical population model describing interindividual variability, at the subject level, data (y) are measured at times t after exposure to dose E . A set of individual characteristics (parameters, θ) also condition the observations. Some of these characteristics

Figure 17.4 General graphical representation of a multilevel population pharmacokinetic model. The “hierarchical” or “multilevel” structure of the model is apparent, with two major components: the subject level and the population level. Symbols: P , prior distributions (only relevant in a Bayesian context); μ , mean population parameters; Σ^2 , variances of the parameters in the population; E , toxicant exposure concentrations; t , experimental sampling times; θ , unknown physiological parameters; ϕ , measured covariates; f , structural pharmacokinetic model; Y , measured drug concentrations (e.g., in plasma); and σ^2 , variance of the experimental measurements. Parameters μ and Σ^2 summarize the distribution of the individual parameters θ across the population.

may be known (e.g., sex, age, genotype), in which case they are considered as “covariates,” but usually some interesting characteristics are unknown and need to be estimated from the data. That estimation can be achieved by data fitting. In Fig. 17.4, unknown quantities are enclosed in circles and known quantities in square boxes. Besides a description of the population variability (which parameters are supposed to vary randomly between subjects), population data analysis requires the definition of two models at the individual level.

- First, a statistical model should link some “predictable” aspects of the data (e.g., their expected values or their variance) to the actual measurements (y). Deviations between measurements and their expected values may be due to limited assay precision, modeling error, or random intraindividual variability. Such deviations are typically assumed to be independent normal or lognormal random variables, with mean zero and variance σ^2 . That variance can be set to a known value (e.g., if analytical precision has been independently assessed and if modeling error is negligible). It can also be estimated along with the other parameters. The model chosen will specify the data “likelihood.” This likelihood is proportional to the probability of the observed data, given a model and its parameter values.

- Second, a PK model, f , should link the chosen “predictable” to E , t , and θ , or any other relevant “explanatory” variable.

At the population level, intersubject variability is described by considering that the individual parameters, θ , are randomly drawn from given statistical distributions, each with population mean μ and population variance $\sum^2$, as described above. Population means and variances are to be estimated together with the parameters θ and the residual variance σ^2 . The preceding mention of population means and variances does not imply that only parametric definition (e.g., Gaussian or log-Gaussian) of the population variability can be used. In fact, choosing a particular distribution shape for the population distribution of a given parameter can be problematic. What if, for example, a Gaussian shape (unimodal by definition) is used when in fact the values fall into two clearly distinct groups in the population? The estimated mean would probably fall in between the two groups but would describe neither of them correctly. An answer to that problem can be found in the use of more flexible nonparametric methods, which aim to estimate the shape itself of the population distribution [166–168].

Uncertainty enters in the above framework in two ways:

- First, through all variance sources aggregated into the residual variance σ^2 (typically, limited assay precision, modeling error, and unmodeled levels of variability). Note that it is possible to disaggregate σ^2 in order to identify separately its various components. For example, a further level in the hierarchy can be defined to deal with intraunit variability [169]. In that case, residual variance can be reduced if intraunit variability is significant. However, some measurement and modeling errors are likely to remain, even with the best available data and models. A side effect of that “noise” is to allow different model parameter values to yield adequate fits to the data (what is meant by adequate is determined by the statistical measurement model). This results in uncertainty about all the quantities estimated in the fitting process (population parameters, individual characteristics, etc., and even σ^2 if it is adjusted). This uncertainty may entangle estimates through fitting-induced correlations, which make it difficult to interpret the results when many parameters are adjusted.
- A less obvious source of uncertainty, which affects the population parameters, is the finite and often small size of the population sample studied. Even if the characteristics of each individual were perfectly known (from perfect data and models), the population parameter values inferred from a nonexhaustive sample would still be affected by uncertainty. For example; in the case of 1,3-butadiene toxicokinetics, the coefficient of variation of the population variance estimate for metabolic clearance was found to be around 50% with a sample of only 10 subjects and is in general inversely proportional to the square root of the number of subjects [148].

17.5.4 Tools for Inference on Population Models

The methods available to calibrate population models fall mostly into two groups: maximum likelihood approaches [168,170] and Bayesian approaches [161,171–173]. Both approaches are reviewed and discussed in Ref. 174.

Bayesian methods extend the maximum likelihood approach by placing prior distributions, hopefully informative, on the various unknown parameters, such as θ , μ , and Σ^2 in the above example (Fig. 17.4). In the Bayesian framework, unknown quantities are considered as random variables and their probability distributions are interpreted in terms of degrees of belief about their possible values. Before analyzing an experiment, a “prior” probability distribution, P , is constructed for each unknown to reflect current knowledge about it. Using a probability distribution to represent prior knowledge gives a unified way to account for precise to vague information available before an experiment. When little knowledge is available on a particular parameter, a noninformative distribution (i.e., flat shaped) can be used. In that case, actually, the Bayesian and the maximum likelihood methods should give similar results. If stronger prior knowledge is at hand, the prior should represent that information as appropriately as possible. Information from the literature tends to relate to average values or variances for a population and is naturally handled in a population model. With a Bayesian approach, such information can be directly used under the form of prior distributions for population parameters such as μ and Σ^2 .

Bayesian approaches have emerged as the best suited for PBPK models, given the large amount of prior information they give access to [14,173]. But as we have seen above, a large amount of that information is already encoded as prior distributions, and updating those distributions with system’s level data, is simply a matter of using Bayesian numerical methods such as MCMC simulations [175]. The availability of those methods has largely contributed to the proliferation of Bayesian analyses in applied statistics during the last 15 years.

To bridge the “bottom-up” PBPK approaches and the “top-down” population PK analysis of clinical data and to accelerate model building and covariate recognition in drug development, a “parameter estimation” module has recently been implemented in the Simcyp Simulator (version 9.30). It allows the PBPK, drug–drug interaction, and ADAM models to be fitted to observed clinical data for the purpose of estimating unknown/uncertain drug or physiological parameters.

17.6 CONCLUSIONS

A priori variability modeling and *a posteriori* population analyses use fundamentally similar models to describe the mechanisms of drug PK and metabolic interactions. Improved numerical algorithms, such as MCMC methods, and computer power are now bridging the gap between the *a priori* and *a posteriori* approaches. For example, PBPK models can now be calibrated and refined using population samples data before being used for prediction of the full population. We have not reviewed the topic of pharmacodynamic drug–drug interactions or variability. The fact is that predictive mechanistic pharmacodynamic models are less advanced than PBPK models. Arguably, they tackle more complex questions, but we are already witnessing advances on that front [176–180], with systems biology approaches potentially able to make a mechanistic continuum between kinetics, metabolism, and cascades of effects [5]. The future should see ever improving PBPK models linked to organ physiology models and cellular effect models. We are progressing toward the development of global predictive analyses of drug safety and efficacy, with ever finer descriptions of individual susceptibility. This trend is congruent with the current drive toward personalized medicine.

18.1 INTRODUCTION

The main principle of drug labeling is to provide the prescriber with sufficient objective information to make informed prescribing decisions. The structure of US drug labels has evolved over time, and in 2006 new regulations were put in place to make the organization and chapter headings of drug labels consistent and easier to understand for both the patient and physician. Nevertheless, the labels have lengthened and the composite book of US labels (the 2011 edition of the PDR) has grown to over 3250 pages of labeling information on over 1116 of the most commonly prescribed drugs. Issues of dosing, drug metabolism, and clinical pharmacology have to be carefully reviewed for any drug prescribed to avoid unwanted consequences. Important issues

Encyclopedia of Drug Metabolism and Interactions, 6-Volume Set, First Edition.

are addressed as “black box warnings” although there is some dispute whether or not this information is used in a consistent manner [1]. The length of the label may also reflect a defensive legal side as well as the more helpful informational aspect. Despite the carefully crafted labeling information, drugs are increasingly prescribed off label, which means using approved drugs in unapproved situations [2].

Modern drugs are fully investigated before approval and marketing and tend to be very robust in dose and rarely need dose modification. This chapter discusses how we reached this state and provides some examples from the past of drugs that were inappropriately dosed or that required dose modification based on variations in drug metabolism or excretion. Recommended drug doses are currently based on a full development program providing appropriate doses to maximize efficacy and minimize safety issues. In addition, a full drug development program uses clinical pharmacology to investigate pharmacokinetics and pharmacodynamics, including potential metabolic variability and drug–drug interactions. The full description of the efficacy, safety, and clinical pharmacology information collected is then presented in the drug labeling for the use of physicians and patients. Whether or not this information leads physicians to make dosing modifications for individual subjects is discussed.

Before considering the impact of drug metabolism, it is worth considering how recommended drug doses are decided; and the factors that may influence that decision both before and after regulatory approval. For new drugs or old drugs for new indications, the process of drug development leads to a choice of dose, dosing interval, and method of administration. Appropriate formulations are then manufactured to satisfy those needs and the definitive clinical trials are usually carried out using those formulations, which are then taken through to marketing.

Selection of new drugs usually involves a choice from a range of chemicals with different physical and chemical properties, leading to potential benefits in terms of absorption, distribution, and elimination. Once selected, the chemical is tested in animals to determine the nature of any toxicity at high doses and the serum levels of drug that are associated with those toxicities. This allows the first use in man using appropriate algorithms to compare kinetics in different species and choosing a dose with an adequate safety margin [3]. From that point clinical pharmacology guides the process, but the minimum dose is considered from observation of efficacy and the maximum dose from the appearance of toxicity or maximum tolerability. This is made easier for drugs with a clear surrogate end point such as measurement of serum cholesterol or blood pressure, but it is harder for drugs with more subjective end points, such as pain, or psychiatric disorders. Thus, at the end of the development program, a recommended dose range is chosen together with appropriate formulations and a full label to guide prescribing.

The basis for the dose range is supported by clinical trials in predominantly healthy subjects, that is, those with the disease of interest but otherwise healthy. Additional studies provide information on absorption, distribution, and elimination; potential interaction with food; drug–drug interactions; and pharmacokinetics in the presence of renal and hepatic impairment. The product is then launched and subsequent information becomes available through postmarketing surveillance, phase 4 clinical trials, and other sources of information. This ultimately leads to changes in the label providing guidance to physicians and users. Thus, information from real world use leads to continuing updates to prescribing information as the product life cycle continues.

18.2 RECOMMENDED DOSE OF DRUGS

The dose of drug chosen, for marketing, at least for small molecules, is usually an arbitrary or compromise dose, dependent on number preferences. For example, a dose of 10 mg of drug a day could have been in a range of 5–15 mg and the number preference was to make a 10-mg dosage form rather than 7.5-, 8-, or 12.5-mg dose. These decisions are to some extent made by market comparisons and also by the risk–benefit profile (lower doses sacrifice efficacy for safety, whereas higher doses are more likely to be efficacious at the potential risk of higher adverse event rates). This lack of precision rarely matters because the variability of serum levels of the same drug in the same individual is usually greater than a small difference in the dose of drug. However, there are a small number of drugs that are very sensitive to variations in serum level, and they may have to be monitored carefully, either by measuring the serum drug level or by measuring the pharmacological action of the drug. Some examples are warfarin, phenytoin, and digoxin.

The US label for warfarin actually lists seven different oral presentations between 1 and 10 mg, as well as a parenteral form, and states that dosage needs to be individualized for each patient by regular measurement of clotting through the INR (international normalized ratio) [4].

Phenytoin has only one slow release form of 100 mg with an initial recommended dose of 300 mg/day and subsequent adjustments up to 600 mg/day. That allows dose adjustment with the objective to prevent seizures without inducing phenytoin toxicity. Because of the narrow therapeutic range, it is advisable to measure phenytoin serum levels until the dose is stable. It appears that the wide interindividual variability is due to CYP2C9 and CYP2C19 variants [5].

Digoxin is similar in its narrow therapeutic range and the manufacturer provides four solid oral doses staged by doubling the previous dose (62.5, 125, 250, and 500 μ g) as well as a liquid capsule and a parenteral form. In the 1970s, the Burroughs Wellcome Company changed the formulation of the branded Lanoxin (digoxin) tablet, unintentionally, making it more bioavailable. This resulted in a number of cases of digoxin toxicity and shows that dose cannot be considered independently of formulation and actual bioavailability [6].

For the vast majority of small molecule drugs, there is a wide therapeutic range so that dose selection is less critical. This has led to a number of examples of excessive recommended doses of drugs continued over many years. The recommended dose of estrogens, for example, was excessive for many years, probably because estrogens were first used in the 1940s and were not subjected to current standards of clinical pharmacology. A paper in 1948 [7] described the dose of ethinyl estradiol (which had just become available in Britain) at around 1 mg/day, whereas the current tablet size is 0.03 mg. It is not clear that the lowest effective dose of the various forms of estrogen has even now been reached, leading to confusion in the literature about the efficacy and hazards of estrogen use in women at different times of pre- and postmenopause [8].

The dose of captopril was initially 150 mg three times daily in the majority of preapproval studies and was initially approved at that level. It was subsequently used at doses closer to 25 mg two or three times daily. The adverse effect profile was reviewed soon after the launch of captopril and showed that rash and taste disturbance were clearly dose-related adverse effects when compared to doses >150 mg/day and <150 mg/day, and the efficacy was maintained at the lower dose [9].

Another area to consider in initial drug dosing is the first-time use in humans. The FDA provides extensive guidance on estimating the initial human dose [3]. This has been an area of relative safety, but a recent experience with a biological has inspired a fresh look at first in man dosing. Tegeneron 1412 is a monoclonal antibody to CD28, which was studied in animals and then caused severe life threatening reactions in all four of the initial volunteers, who were all dosed at the same time. A representative critique suggests that further nonclinical work should have been carried out before initiating human dosing and the initial dose was too high [10].

On the basis of this history, regulators have clarified and expanded the clinical pharmacology requirements for new drugs and new formulations to lead to a fuller understanding of desirable dosing. This leads to a large amount of information to include in the label for drugs that is designed to help good prescribing.

18.3 FORMULATION AND METHOD OF ADMINISTRATION

The concept of a dose is based on the formulation and method of administration. Some drugs such as fenofibrate have been reformulated to have different doses in the different formulations each providing similar activity. Fenofibrate is a relatively insoluble molecule, so altering the physical properties, such as by micronizing the active pharmaceutical ingredient changes the bioavailability. This leads to different dosages depending on the type of formulation with doses of 48 and 145 mg for the Tricor brand; 130 mg for the Antara brand; 160 and 200 mg for the Lofibra brand; and 45–135 mg for Trilipix a delayed release form. In addition, the absorption of fenofibrate is increased by 35% when given with food for all of the brands except Trilipix.

18.4 AGE

An understanding of dosing is needed at both ends of the age spectrum. It has been traditional in children to use drugs studied in adults and adjust the dose in some nonspecific way. Since 1997, the pharmaceutical industry has been encouraged to carry out studies in children because of the Food and Drug Administration Modernization Act (FDAMA), which provides additional six months of marketing exclusivity in return. This has provided more appropriate information to prescribe in children based on actual pediatric experience in the disease of interest.

As individuals get older, their renal function deteriorates leading to a need for specific dosing guidance. Groups of interest are subjects with ages from 65 to 75, 75 to 85 and older than 85 [11]. One of the first drug problems in the elderly occurred with the drug benoxaprofen, a nonsteroidal anti-inflammatory agent. Benoxaprofen was initially approved at a single dose of 600 mg/day but turned out to have a much longer half-life in the elderly population, particularly, in subjects over 80 years of age. A series of subjects, all aged over 80 years, had cholestatic jaundice and died probably related to the excessive benoxaprofen serum levels seen in this population [12]. A study suggested that the drug was being overdosed particularly in the elderly [13]. This episode led to the requirement for pharmacokinetic studies in the elderly to ensure the dosing is consistent with the younger population and adverse events are kept to a minimum [14].

18.5 SIZE AND WEIGHT

Most labeling is silent on dose adjustments for weight or BMI (body mass index). However, some attempts have been made to study different doses for different sized people. A study of heparin suggested that if doses were modified, it would lead to more rapid anticoagulation and reduced bleeding, but the concept has not been widely adopted [15]. Anticancer drugs are usually prescribed based on body surface area and are labeled as a dose per meter squared. This concept was started in the 1950s but has been questioned [16]. It has also been suggested that the interpretation of body surface area leads to underdosing of anticancer medication for the treatment of breast cancer, particularly, in subjects of low socioeconomic status [17]. Some other classes of drugs, including anesthetic agents, do have nomograms for modifying dose based on weight or BMI; but the best way of estimating the dose adjustment still has to be established [18].

18.6 RENAL IMPAIRMENT

It is clear that if a drug is excreted by the kidneys, either as the unchanged parent drug or as major metabolites, the plasma, blood, and tissue levels are likely to rise in the presence of increasing renal impairment. That has led the FDA to insist on estimating this increase in subjects with renal impairment for all chronic use drugs whether or not they are renally excreted [19]. The results of these small pharmacokinetic studies are then reported in the label with statements such as “use with caution in subjects with renal impairment.”

However, there are some drugs that become toxic as the serum levels increase, and this has led to various methods for monitoring and adjusting dose in response to renal impairment. Aminoglycoside antibiotics have traditionally been used in renal impairment even though they cause both ototoxicity and nephrotoxicity at high systemic levels. An early nomogram for gentamicin was published in 1972 that allows the dose to be modified to maintain efficacy in all degrees of renal impairment and hemodialysis, and the results were very successful in terms of outcome. Another drug that has to be used with caution in subjects with renal impairment is lithium. As lithium toxicity impairs renal function, it exacerbates the problem, and careful monitoring of lithium levels is important. It may be necessary to use hemodialysis to reduce lithium toxicity [20].

Because of the general concerns about using drugs in renal impairment, efforts have been made to offer guidelines for such prescribing that go beyond the approved label [21]. Such advice is almost certainly used in renal units where the issues are fully understood and there is very little margin of error. However, in the more general medical environment, the issues of renal impairment are probably underestimated [22]. Physicians seeking clarity on the appropriate dosing guidance in renal impairment may find confusion in the various official and secondary sources of information [23].

Renal physicians are comfortable using a limited number of drugs in subjects with severe renal failure or on dialysis, but there is some confusion in the general population who may incidentally have mild or moderate renal impairment. Although there are theoretical concerns, it does not appear that there is a major safety issue for the majority of drugs and those drugs that are well known to cause problems have appropriate dose adjustment guidelines. The use of language such as “use with caution” is probably too vague to be useful in practice.

18.7 HEPATIC IMPAIRMENT

Many drugs are metabolized by the liver either into inactive metabolites or into active moiety. It is therefore recommended that such drugs have pharmacokinetic studies in mild, moderate, and severe liver function as measured by the Child-Pugh classification. Unlike renal disease, there is no simple factor that determines the degree of liver function. The study design recommended by the FDA [24] involves studying the drug in at least eight usable subjects with the relevant amount of hepatic dysfunction and an age- and sex-matched control group. This provides pharmacokinetic information but does not really address whether or not there are consequences of chronic use in such subjects and whether or not the dose needs adjusting. There are some drugs that may be needed to modulate the hepatic disease such as prednisolone and other drugs that are needed for chronic or acute therapy in subjects who happen to have some degree of hepatic impairment, but in general, it is easier to avoid or reduce the use of therapeutic drugs in subjects with marked hepatic impairment.

A full discussion of the various factors involved in dose adjustments in hepatic dysfunction has been published [25]. They include protein binding as well as increases and decreases in efficacy as a result of potential pharmacokinetic changes in both the parent drug and its metabolites. In addition, safety considerations may be intensified in subjects with hepatic impairment. This is a consideration particularly with antineoplastic drugs, which may also contribute to the hepatic toxicity and resulting dysfunction. However, there is no clarity in dose adjustments for particular drugs even though the pharmacokinetic changes may be clear resulting in a clinical dosage trial in each subject as suggested by some authors [26].

18.8 METABOLIC PATHWAYS

The knowledge of metabolism of individual drugs is a major part of drug discovery and development starting with *in vitro* microsomal studies and following through with extensive study of metabolic pathways and the resulting potential drug–drug interactions. This is discussed extensively in this encyclopedia. Drugs with high potential for interactions are rarely chosen to develop further. However, this is an area where drug labeling is more precise and the results of pharmacokinetic drug–drug interaction studies are accurately presented. There are two potential directions of concern. Does the drug interact with other drugs because of competition, stimulation, or inhibition of a particular pathway that may be needed for the metabolism of the other drug? Alternatively, does the other drug interfere with the metabolism of the new drug because of competition, stimulation, or inhibition of the relevant metabolic substrates? This leads to presentation of the data in the label with statements about the pharmacokinetic changes.

If we use Lipitor (atorvastatin) as an example of a commonly used drug, the dosing consequences from the label can be seen.

Under the heading of drug interactions, we see the following statements:

The risk of myopathy during treatment with statins is increased with concurrent administration of fibric acid derivatives, lipid-modifying doses of niacin, cyclosporine, or strong CYP3A4 inhibitors (e.g., clarithromycin, HIV protease inhibitors, and itraconazole).

No numbers are presented to help assess the increased risk. Is it from 0.001% to 0.002%, which is a doubling, but remaining very rare; or is it from 5% to 6%, a smaller increase of the population but one that will affect many more people? Many physicians use fibrates and atorvastatin together and a combination tablet has been under development [27] with results that were encouraging and showed no increase in myopathy in a relatively small study.

The metabolism of modern drugs is well understood allowing fairly accurate statements to be made in the label.

Strong Inhibitors of CYP3A4. Lipitor is metabolized by cytochrome P450 3A4. Concomitant administration of Lipitor with strong inhibitors of CYP3A4 can lead to increase in plasma concentrations of atorvastatin. The extent of interaction and potentiation of effects depend on the variability of effect on CYP3A4.

Clarithromycin. Atorvastatin AUC was significantly increased with concomitant administration of Lipitor 80 mg with clarithromycin (500 mg twice daily) compared to that of Lipitor alone. Therefore, in patients taking clarithromycin, caution should be used when the Lipitor dose exceeds 20 mg.

Combination of Protease Inhibitors. Atorvastatin AUC was significantly increased with concomitant administration of Lipitor 40 mg with ritonavir plus saquinavir (400 mg twice daily) or Lipitor 20 mg with lopinavir plus ritonavir (400 + 100 mg twice daily) compared to that of Lipitor alone. Therefore, in patients taking HIV protease inhibitors, caution should be used when the Lipitor dose exceeds 20 mg.

Itraconazole. Atorvastatin AUC was significantly increased with concomitant administration of Lipitor 40 mg and itraconazole 200 mg. Therefore, in patients taking itraconazole, caution should be used when the Lipitor dose exceeds 20 mg.

So, it is clear that despite the known interaction, it is reasonable to use up to 20 mg Lipitor, and it may even be useful to use higher doses. How are the individual physician and patient to decide? Although no formal survey has been performed discussion with a number of practicing physicians suggests that each subject is considered in a therapeutic environment with reductions in dose to alleviate adverse events and increases in dose to maintain the desired therapeutic effect so the language in the label may be ignored unless issues arise.

Grapefruit Juice It contains one or more components that inhibit CYP3A4 and can increase plasma concentrations of atorvastatin, especially with excessive grapefruit juice consumption (>1.2 L/day).

Does this mean that subjects should not take grapefruit juice or that they should take grapefruit juice to increase the efficacy of Lipitor? The clinical answer suggests that it depends on how the subject is responding although this statement seems to cause concern to subjects on atorvastatin.

Cyclosporine Atorvastatin and its metabolites are substrates of the OATP1B1 transporters. Inhibitors of the OATP1B1 (e.g., cyclosporine) can increase the bioavailability of atorvastatin. Atorvastatin AUC was significantly increased with concomitant administration of Lipitor 10 mg and cyclosporine 5.2 mg/kg/day compared to that of Lipitor alone. In cases

where coadministration of Lipitor with cyclosporine is necessary, the dose of Lipitor should not exceed 10 mg.

The advice is clear but the maximum AUC increase is not mentioned to help understand whether to go to 20 mg Lipitor if the desired efficacy is not achieved.

Rifampin or Other Inducers of Cytochrome P450 3A4 Concomitant administration of Lipitor with inducers of cytochrome P450 3A4 (e.g., efavirenz and rifampin) can lead to variable reductions in plasma concentrations of atorvastatin. Owing to the dual interaction mechanism of rifampin, simultaneous coadministration of Lipitor with rifampin is recommended, as delayed administration of Lipitor after administration of rifampin has been associated with a significant reduction in atorvastatin plasma concentrations.

This is the most specific type of labeling language giving clear and undeniable advice, but this is the most unusual form.

Digoxin When multiple doses of Lipitor and digoxin were coadministered, steady state plasma digoxin concentrations increased by ~20%. Patients taking digoxin should be monitored appropriately.

This advice refers to digoxin rather than Lipitor and clearly implies that the dose of digoxin may need to be lowered but does not advise how best to do that. Discussions suggest that a 20% increase in digoxin serum concentrations are considered generally insignificant and digoxin dosing would not be modified unless there was an evidence of toxicity.

Oral Contraceptives Coadministration of Lipitor and an oral contraceptive increased AUC values for norethindrone and ethinyl estradiol. These increases should be considered when selecting an oral contraceptive for a woman taking Lipitor.

The implication is that lower dose oral contraceptives should be chosen, but no comments are made on whether the efficacy of those lower doses will be sustained. This would appear to be a relatively unusual situation, as the vast majority of subjects treated for excess lipids are postmenopausal. However, it becomes a serious issue in those subjects with familial hypercholesterolemia. Other statins are available that are not modulated through cytochrome P450 3A4 and that may be an alternative solution although not specifically mentioned in the label for atorvastatin.

Warfarin Lipitor had no clinically significant effect on prothrombin time when administered to patients receiving chronic warfarin treatment.

This is an important labeling statement because it discusses the outcome, that is, prothrombin time, rather than the usual presentation of pharmacokinetic drug levels.

The conclusion is that a good deal of clinical pharmacology takes place to help understand the metabolism of the drug of interest. However, whether that can be translated into practical clinical advice remains unclear, and the physician must then decide on how to deal with each drug–drug interaction issue.

18.9 GENETIC POLYMORPHISM

Variations in cytochrome P450 metabolic pathways are modified by polymorphic genetic variability. These provide opportunities to modify the drug dose and hence individualize drug therapy, to reduce adverse events and maintain efficacy. A review of the subject suggests that adverse events could be reduced, but the practical implications are not contained in current labeling [28]. A more recent paper confirms these findings and argues that science be used prospectively in drug research [29].

Some examples may be helpful. Tramadol is a centrally acting analgesic that is by itself active and has an active metabolite *O*-desmethyl-tramadol (M1). The *O*-demethylation is catalyzed by cytochrome P450 2D6 and the *N*-demethylation is catalyzed by CYP2B6 and CYP3A4. There is a wide variability in pharmacokinetics because of CYP genetic polymorphism [30]. This is reflected in the current Tramadol label, which reads as follows:

“The formation of the active metabolite, M1, is mediated by CYP2D6. Approximately 7% of the population has reduced activity of the CYP2D6 isoenzyme of cytochrome P-450. Based on a population PK analysis of Phase I studies with immediate-release tablets in healthy subjects, concentrations of tramadol were approximately 20% higher in “poor metabolizers” versus “extensive metabolizers,” while M1 concentrations were 40% lower. *In vitro* drug interaction studies in human liver microsomes indicate that inhibitors of CYP2D6 (fluoxetine, norfluoxetine, amitriptyline, and quinidine) inhibit the metabolism of tramadol to various degrees, suggesting that concomitant administration of these compounds could result in increases in tramadol concentrations and decreased concentrations of M1. The full pharmacological impact of these alterations in terms of either efficacy or safety is unknown.”

Irinotecan is an anticancer drug which can cause toxicity including leucopenia and diarrhea. Irinotecan is metabolized to form an active metabolite SN-38 which is then further metabolized by UDP-glucuronosyltransferase (UGT) 1A1 enzyme. There is genetic polymorphism of the (UGT) 1A1 enzyme [31]. The label states the following:

“The metabolic conversion of Irinotecan to the active metabolite SN-38 is mediated by carboxylesterase enzymes and primarily occurs in the liver. SN-38 is subsequently conjugated predominantly by the enzyme UDP-glucuronosyl transferase 1A1 (UGT1A1) to form a glucuronide metabolite. UGT1A1 activity is reduced in individuals with genetic polymorphisms that lead to reduced enzyme activity such as the UGT1A1*28 polymorphism. Approximately 10% of the North American population is homozygous for the UGT1A1*28 allele. In a prospective study, in which Irinotecan was administered as a single-agent on a once-every-3-week schedule, patients who were homozygous for UGT1A1*28 had a higher exposure to SN-38 than patients with the wild-type UGT1A1 allele SN-38 glucuronide had 1/50 to 1/100 the activity of SN-38 in cytotoxicity assays using two cell lines *in vitro*. The disposition of Irinotecan has not been fully elucidated in humans. The urinary excretion of Irinotecan is 11% to 20%; SN-38, <1%; and SN-38 glucuronide, 3%. The cumulative biliary and urinary excretion of Irinotecan and its metabolites (SN-38 and SN-38 glucuronide) over a period of 48 hours following administration of Irinotecan in two patients ranged from approximately 25% (100 mg/m²) to 50% (300 mg/m²).”

“When administered as a single-agent, a reduction in the starting dose by at least one level of Irinotecan hydrochloride injection should be considered for patients known to be homozygous for the UGT1A1*28 allele. However, the precise dose reduction in this patient

population is not known and subsequent dose modifications should be considered based on individual patient tolerance to treatment.”

It would appear that the science continues to improve to help understand how genetic polymorphism explains differences in toxicity and to some extent efficacy. However, based on these two examples, it is still not possible to adequately label the proposed change in dose with any precision.

18.10 ETHNIC DIFFERENCES

Ethnic factors have become an issue in drug development with a guideline generated from the International Congress on Harmonization (ICH) [32]. It is hard to tease out the effects of ethnic factors from genetic polymorphism as discussed in the last section. Ethnic factors include intrinsic factors such as genetics and metabolism and extrinsic factors such as diet, medical practice, and use of concomitant drugs, tobacco, or alcohol. There are probably no pure ethnic factors but the proportion of the population with a particular genetic polymorphism varies in different ethnic populations. It is clearly desirable to include as diverse a population as possible in clinical trials to help understand and anticipate any ethnic differences, but the practical labeling consequences are less clear. It is apparent that some drugs have been dosed lower in Japan than the United States, but there is greater concordance in dosing between Europe and the United States although there are some exceptions [33]. A full review of the literature underpinning ethnic differences has been carried out, and includes questions on the precision of the ethnic group being tested as well as differences in methodology used in different studies [34]. Modern drug development incorporates a diverse population with multicentered multinational studies becoming the norm in phase 3. However, the interpretation of this diverse data does not lead to individual drug labeling advice.

18.11 INDIVIDUALIZED DRUG THERAPY

Much has been written about personalized medicine but with a few exceptions it remains a dream rather than a reality. Looking at mean differences resulting from drug therapy in clinical trials and comparing with placebo has been the standard for 40 years. Defining subpopulations with the appropriate results from genetic testing of some description will result in several different subpopulations making recruitment for clinical trials more complex. This has been established with a few efficacy markers such as Herceptin targeting HER2, Erbitux targeting EGFR for metastatic colorectal cancer, and Gleevec targeting the cell surface tyrosine kinase receptor in gastrointestinal cells [35]. Whether it is equally possible to target subpopulations who are more likely to have adverse events remains to be seen and will present increasing complexity in clinical trial design. One of the issues is that it may be becoming easier to predict changes in serum level of active drug or active metabolites, as has been discussed, because of increasing knowledge of genetic diversity, but translating these values into meaningful dosing information remains difficult.

18.12 CONCLUSION

The drug development process leads to increasing knowledge about the metabolism of drugs, and this information is usually collected during drug development before drugs being marketed. The drug development process is intended to exclude drugs that have problematic metabolism or drug–drug interactions, and modern drugs are usually robust in their dosing regardless of the medical issues of the subjects taking the drugs. The labeling process is formalized, but it would appear not to be terribly helpful in practice in answering questions about dose modifications. Terms such as *use with caution* are prolific but all drugs should be used with caution so the term is almost meaningless. Questions on particular drug dosing have suggested that labeling be more precise and kept simple but that full information be made available so physicians can make informed decisions [36]. The prospect of individualized medicine remains an opportunity rather than a reality. In addition, it is important that medical professionals get more training on drug use at medical school and through ongoing continuing medical education, so they can make fully informed and appropriate dosing decisions [37,38].

13.1 INTRODUCTION

When developing a new drug, the goal is to produce therapeutic agents that are safe and effective at treating or preventing diseases. It is estimated that over 10% of drugs fail in clinical trials because of pharmacokinetic (PK) reasons and unexpected drug–drug interactions [1]. As such, the US Food and Drug Administration (FDA) guidelines emphasize the identification of metabolic pathways, relevant major metabolites, and the potential for drug–drug interactions of new chemical entities (NCEs), where metabolism is the principal route of elimination [2]. Consequently, preclinical drug metabolism and drug–drug interaction studies are critical for the development of orally administered drug candidates.

A number of liver-derived *in vitro* systems, such as slices, subcellular fractions (microsomes), and primary and immortalized hepatocytes, are typically utilized to assess the metabolism and toxicity of new drugs. Microsomes derived from preclinical species and human livers are the screening model of choice for assays based on high throughput drug metabolism, and these are increasingly being replaced or complemented by fresh isolated or cryopreserved primary hepatocytes [3,4]. Before utilizing primary hepatocytes for *in vitro* drug testing, it is helpful to appreciate the key architectural features and molecular factors that determine their unique phenotype *in vivo*. Hepatocytes from adult mammalian liver are highly differentiated epithelial cells and perform a wide variety of functions related to absorption, metabolism, and excretion of drugs and other xenobiotics. The cytoplasm is usually enriched in rough endoplasmic reticulum due to the secretory nature of the cells. There are also numerous areas of smooth endoplasmic reticulum which contain most of the enzymes involved in the metabolism of xenobiotics, especially the cytochrome P450 (P450) and uridinediphospho (UDP)-glucuronosyltransferase enzymes. Fat droplets may appear as inclusions in the cytoplasm, particularly in hepatocytes isolated from donors with a high body mass index (BMI). Hepatocytes are highly polarized cells and exhibit distinct domains on the plasma membrane, specifically the sinusoidal domain on the blood sides and the canalicular domain on the bile side, which is crucial for establishing the vectorial uptake, metabolism, and excretion of xenobiotics from the liver. Within the hepatocyte, there is a polarized localization of cytoplasmic organelles, such as the endoplasmic reticulum, Golgi apparatus, and the cytoskeletal elements, which aids in establishing and maintaining the overall architecture and therefore, functions of the cell [5,6].

Metabolism of drugs and other xenobiotics primarily takes place in the hepatocytes and usually occurs in two phases. Phase I metabolism involves reactions such as oxygenation, oxidation, reduction, dehalogenation and hydrolysis, that expose or introduce functional groups into the lipophilic molecules, thereby making them more hydrophilic and more readily excretable [7]. Phase II metabolism (conjugation enzymes) comprises synthetic reactions in which small endogenous molecules (e.g., glucuronic acid, glutathione, sulfate, glycine, and other amino acids) are added to the functional groups of xenobiotics or their phase I metabolites, thus making them even more polar and readily eliminated. Phase I metabolism does not necessarily precede conjugation and direct phase II metabolism, without prior oxidation/hydroxylation is common. For example, diclofenac is metabolized by direct conjugation of the parent drug as well as oxidation of the aromatic rings, usually followed by conjugation [8]. Similarly, the nonsteroidal anti-inflammatory drug (NSAID) carprofen is directly conjugated to form an ester glucuronide, and this represents the only significant pathway of metabolism [9]. Conjugated metabolites are actively transported out of the hepatocyte by efflux pumps that reside in the basolateral and canalicular (apical) membranes and excreted via bile and urine [7].

Historically, one of the major obstacles to determine the pharmacological and toxicological effects of new drugs on the liver has been the lack of adequate *in vitro* model systems. Therefore, a major goal of pharmaceutical researchers studying drug metabolism and hepatotoxicity has been to develop *in vitro* cell models that simulate *in vivo* conditions. Short-term metabolism and safety studies can be conducted with isolated hepatocytes and liver slices, as the incubation medium, and cells can be easily separated for analysis of drug metabolites [10,11]. When isolated and handled properly, primary hepatocytes from adult liver contain a broad complement of

metabolizing enzymes and transport proteins, organized in a physiologically relevant context and regulated via cellular processes that occur within the liver *in vivo* (e.g., nuclear-hormone-mediated xenosensors) [12].

It must be appreciated, however, that the behavior of the liver is, to some extent, dependent on its anatomy, and this cannot be mimicked by standard suspension culture methods. Cells in suspension inevitably lack various features of the organization of hepatocytes in the intact liver, and they cannot be used for evaluating drug-induced changes in gene expression (i.e., enzyme induction) due to their refractory nature while in suspension [13,14]. Moreover, suspended cells are spherical, entirely covered with microvilli and lack distinct membrane regions such as the sinusoidal versus canalicular domains. In addition, they lack the contact with extracellular matrix or cell–cell contacts (with either other hepatocytes or nonparenchymal cells), which appear to be important for maintaining differentiated function *in vivo* [5,12].

The development of more physiologic hepatocyte culture systems has permitted major advances in the study of hepatic gene regulation and cellular differentiation [14,15]. Many related molecular and biochemical pathways are restored and respond to experimental manipulation only after a period of many days in culture. Therefore, a major advantage of the hepatocyte culture systems compared to other *in vitro* liver preparations is their relative longevity of several days, as compared to hours for perfused liver, liver slices, or suspensions of isolated hepatocytes. Another advantage of primary hepatocyte culture, as compared to freshly isolated suspensions, may be that deficiencies of the latter, resulting from damage of the cell membrane by the collagenase treatment, are resolved during the early stages of culture. It has been suggested that recovery might include restoration of cell polarity, some hormone receptors [14,16,17], rates of protein synthesis [18], restoration of normal intracellular ions and glutathione levels, repair of DNA damaged during cell isolation [19], removal of proteolytic enzymes that may have persistent effects in fresh suspensions [20,21] and removal (as nonattached cells) of any residual damaged hepatocytes.

In addition to the repair of damage, recovery of polarity, and restoration of cell–cell interactions, a preincubation period in monolayer culture before initiating studies may also allow better definition of experimental variables by minimizing effects of prior exposure to hormones or nutrients *in vivo*, especially for primary human hepatocytes [14]. Another special advantage of the hepatocyte culture systems compared to cell suspensions or liver slices is the ease with which cells can be examined using today's high content microscopic imaging techniques, so that structural and subcellular changes induced by exposure to a drug can be readily detected [22]. Likewise, the regulation of cell–cell contacts and the mechanisms involving their re-establishment can be studied in cell culture [5]. Similar studies would be virtually impossible to perform using other *in vitro* model systems.

For applications requiring longer experimental periods, cells stably adapted to a defined *in vitro* environment, or where cell architecture and polarity are likely to be important and more sophisticated culture systems may be required for *in vitro* studies. Moreover, for investigating the hepatotoxic effects of drugs, especially on growth control, changes in gene expression, and bioaccumulation, the ability to maintain functional hepatocytes for many days or even months can be essential. For example, culturing hepatocytes in primary sandwich culture between two layers of extracellular matrix proteins (e.g., collagen type I and Matrigel) dramatically prolongs the longevity of cultures and retains many of the hepatocyte-specific functions [23]. Culturing hepatocytes

on collagen, with and without the overlay, results in morphologically distinct hepatocytes with relatively flattened nonoverlaid cells, while in sandwich culture, hepatocytes form aggregates and retain their cuboidal shape [3]. Sandwich-cultured hepatocytes can form extensive, functional bile canaliculi, while these are minimal in the absence of the overlay [24].

With the increased knowledge of the molecular and cellular factors that dictate hepatocyte structure and function *in vivo*, improved isolation, incubation, and cell culture techniques have greatly expanded the number of applications for hepatocytes during the drug discovery and development process [3,25–27]. In this chapter, several standard approaches are described for utilizing primary hepatocytes in suspension or monolayer culture to address specific issues related to hepatic metabolism, transport, and toxicity.

13.2 METABOLIC STABILITY OF DRUG CANDIDATES

13.2.1 Background

Liver-derived systems, such as microsomes, S9 fractions, and intact hepatocytes are routinely utilized to assess the metabolic stability of drug candidates. The use of intact hepatocytes is advantageous because of the presence of the major drug-metabolizing enzymes, xenobiotic transporters, and relevant cofactors [12]. Compounds can be screened and rank ordered according to *in vitro* intrinsic clearance (CL_{int}) values obtained from hepatocyte-based metabolic stability studies and *in vivo* CL_{int} extrapolated. For some therapeutic areas (e.g. neuropathic pain, Parkinson's disease and osteoporosis), long half-life drugs ($T_{1/2}$) with appropriate target potency and volume of distribution (V_d) are desirable, so that once per day or once per week dosing can be achieved [28,29]. In other instances, a short $T_{1/2}$ is desired as in the case of prodrugs or drugs for insomnia, where it is important to have a short $T_{1/2}$ so that there is no residual drowsiness during the day. Metabolic screening assays enable synthesis of more (or less) stable compounds through structure–activity relationships and prevent the progression of labile compounds prior to more costly *in vivo* studies.

13.2.2 Experimental Approaches

In vitro CL_{int} can be calculated by evaluating metabolite formation or substrate depletion using microsomes and hepatocytes [30,31]. Direct comparisons between these *in vitro* systems indicate that hepatocytes are the superior system. For metabolic stability experiments using the metabolite formation approach, a range of substrate concentrations are employed with a set of protein concentration and incubation time. The Michaelis–Menten parameters V_{max} and K_m are estimated and CL_{int} calculated according to the following equation:

$$CL_{int} = \frac{V_{max}}{K_m}$$

Information regarding metabolites is required when using this method and in some cases, authentic metabolite standards are not available to determine formation rates [30]. Furthermore, linear incubation conditions with respect to protein content and incubation time need to be employed to ensure parent depletion is not greater than 10% [31]. The

substrate depletion approach utilizes a single low concentration assumed to be much lower than the K_m value. Typically, hepatocytes or microsomes are incubated with a substrate concentration of $1\ \mu M$ and the disappearance of parent compound monitored over several time points. Monoexponential kinetics is assumed as CL_{int} is a function of the first-order rate constant, k . This approach is also referred to as the *in vitro* half-life ($t_{1/2}$) method and the equation used to calculate CL_{int} is

$$CL_{int} = \frac{0.693}{t_{1/2}} \times \frac{V}{N}$$

where $k = 0.693/t_{1/2}$, V is the incubation volume, and N is the number of cells [32,33].

The area under the concentration versus time curve is at times incorporated within similar equations derived from the substrate depletion method [34]. Assuming that the *in vitro* clearance process follows first-order kinetics, CL_{int} is calculated from the ratio of the initial amount of the test compound minus the amount remaining after 2 h of incubation and the corresponding *in vitro* AUC (area under the curve) between 0 and 2 h. In contrast to metabolite formation methodology, this approach is most effective when at least 20% of parent compound is metabolized over the incubation period [31].

The substrate depletion method is simple and amenable to use in an early discovery setting and microsomes or hepatocytes can be used. The advantage of using hepatocytes is that unlike microsomes that only extrapolate biotransformation reactions carried out by P450 enzymes, the contribution of phase II enzymes to metabolism is also assessed [35]. The use of microsomes poses the risk of underestimation of *in vivo* CL_{int} if metabolic elimination routes other than P450s predominate *in vivo*. Also, if active uptake is required for transport of drug to the enzymatic active site, this factor would be missed entirely by the use of microsomes, leading to overestimation of CL_{int} . Alternatively, liver S9 fractions could be utilized, as these contain both microsomes and cytosol. However, S9 fractions lack membranes as well as the multiple cofactors needed for the phase I and phase II reactions, thereby offering limited advantage over microsomes and the disadvantage of adding multiple relatively unstable cofactors [35]. Healthy hepatocytes with the complete cellular machinery including the additional required cofactors and membrane transporters provide the most complete system for conducting metabolic stability measurements.

13.2.3 Metabolism in Fresh and Cryopreserved Suspensions

The availability of healthy cryopreserved hepatocytes has facilitated the use of these cells in routine drug disposition studies by lessening the issues related to availability of fresh tissue. Moreover, these cells have the added advantage of consistency, as hepatocytes isolated from the same liver can be used multiple times, over a period of time [35–37]. We used the substrate depletion method to estimate *in vitro* CL_{int} in freshly isolated human hepatocytes and cryopreserved human hepatocytes processed from the same donor and calculated values in suspensions and monolayers. Our data demonstrated that metabolic activities were statistically similar between freshly isolated and cryopreserved human hepatocytes from the same preparation. We recommend that fresh or cryopreserved hepatocytes may be used for these studies, as these have comparable metabolic capacity. It is important to include the same positive controls across experiments to ensure the integrity of the individual hepatocyte preparation and validity of experimental conditions.

We prepared primary human hepatocytes from three separate tissue samples and used a portion of each preparation immediately after isolation or brief storage (<24 h) in preservation medium or after at least one month of cryopreservation. Both freshly isolated and cryopreserved hepatocytes from each preparation were subsequently characterized for metabolic activity of the major drug-metabolizing enzymes as per the methods shown in Table 13.1. The resulting metabolic activities of fresh and cryopreserved human hepatocytes from the same preparation were comparable, and statistically significant differences were not observed between activities of specific isoforms (Figure 13.1). The observed differences in metabolic activity between the individual hepatocyte preparations are due to interdonor variability and not cryopreservation. These data demonstrate that functional drug-metabolizing enzymes are maintained in

TABLE 13.1 Incubation Conditions for specific activity

Enzyme	Probe Substrate	Concentration (μM)	Incubation Time (min)
CYP1A2	Phenacetin	100	15
CYP2B6	Bupropion	500	15
CYP2C9	Diclofenac	25	15
CYP2C19	S-Mephenytoin	250	30
CYP3A	Testosterone	200	15
UGT	7-Hydroxycoumarin	100	30

Substrate incubations were performed with human hepatocytes in suspension at a density of 0.50×10^6 cells/mL in multi-well plates. Incubations were terminated by freeze on contact or with organic and samples analyzed by HPLC or LC/MS/MS analyses to determine specific activity.

Figure 13.1 Enzyme-specific activities in freshly isolated and cryopreserved human hepatocytes from the same donor. The data represents three separate hepatocyte preparations (1, 2, and 3). The gray bars represent fresh hepatocytes and the black bars cryopreserved hepatocytes from the same preparation. Bars represent mean $\pm$ standard deviations of triplicate determinations. Missing error bars are indicative of duplicate determinations. Assay conditions are provided in Table 13.1.

cryopreserved human hepatocytes. Next, we assessed the feasibility of using cryopreserved human hepatocytes for metabolic stability evaluations. Six compounds that covered a range of known metabolic pathways were evaluated in hepatocyte preparations isolated from one donor liver. Phenacetin, midazolam and dextromethorphan were chosen as representative examples of moderate to high turnover compounds and tolbutamide (TLB) and diazepam (DZP) represented compounds belonging to a low turnover class. The substrate benzydamine was chosen as a probe for flavin-containing monooxygenase (FMO) activity to assess non-P450 activity in fresh and cryopreserved human hepatocytes. The intrinsic clearance results for moderate to high turnover compounds were comparable between fresh and cryopreserved suspensions (Table 13.2). In our studies, low turnover substrates proved challenging in short-term suspension studies, as reliable CL_{int} values were not attainable and R^2 values from linear regression analyses were below acceptable ranges (data not shown). Metabolic turnover percentages for TLB and DZP generally did not reach the 20% or greater levels that are essential when using this method [31,38].

To alleviate the possibility of severely reduced viability as a reason for decreased metabolism, cell viability was assessed immediately after thawing and removal of cryopreservation medium (fresh hepatocytes) or postthaw (cryopreserved hepatocytes) and also after a 2 h of incubation at 37°C. Viabilities at the onset of incubations were 77% and 78% for fresh and cryopreserved hepatocytes, respectively. Less than 5% loss in cell viability was observed during the incubation period for fresh hepatocytes, and a 6% decrease in viability was observed in cryopreserved hepatocytes. Our results demonstrate that cryopreserved human hepatocytes are good tools for short-term intrinsic clearance experiments and demonstrate particular suitability for moderate to high turnover compounds. As more drugs are identified as substrates of non-P450 pathways, it is critical to have confidence in the metabolic competency of cryopreserved hepatocytes as an *in vitro* tool for studying these pathways. We have conducted metabolic stability studies in hepatocyte suspensions for up to 4 h in culture. We found that incubating hepatocytes for extended periods of time in suspension cultures (i.e., >4 h) causes unacceptable drops in viability (>20%) and a differential loss of phase II metabolic rates compared to those for phase I reactions.

13.2.4 Metabolism in Cultured Fresh and Cryopreserved Primary Human Hepatocytes

In vitro metabolic stability measurements in suspension hepatocytes often underpredict *in vivo* CL_{int} , particularly for low turnover compounds. For orally administered candidate drugs, prediction of *in vivo* CL_{int} is required for dose estimations required to achieve appropriate PK for target pharmacological activity. In these cases, short-term *in vitro* suspension assays in which the substrate depletion method is used may not be applicable for CL_{int} predictions. Griffin and Houston proposed using monolayer cultures as an alternative to suspensions for estimating intrinsic clearance [39]. In their studies, seven compounds were assessed in rat suspensions and monolayers including low turnover substrates *S*-warfarin and tolbutamide and the data demonstrated that CL_{int} can be effectively measured at below 0.1 $\mu\text{L}/\text{min}/10^6$ cells.

We assessed the metabolic stability of six compounds in human hepatocyte monolayers isolated from a single donor liver. The moderate to high turnover compounds

TABLE 13.2 Comparison of Intrinsic Clearance Values Obtained in Freshly Isolated and Cryopreserved Hepatocytes Suspensions and Cultures Processed from the Same Donor Tissue

Substrate	Fresh or Cryopreserved	Hepatocyte Monolayers			Hepatocyte Suspensions			Observed <i>In Vivo</i> CL (mL/min/kg)

Abbreviations: BNZ, benzydamine; DXT, dextromethorphan; DZP, diazepam; MDZ, midazolam; PB, phenobarbital; PHN, phenacetin; TLB, tolbutamide; N.R. not reported.

Primary human hepatocytes cultures and suspensions were incubated with a low concentration of substrate (0.5 or 1 μM) and intrinsic clearance values determined from linear regression analyses of disappearance of parent versus time profiles. *In vitro* clearances were scaled to predicted hepatic clearance as described within the text.

^aStringer *et al.* [46].

^bBlanchard *et al.* [40].

^cMcGinnity *et al.* [32].

^dObach *et al.* [33].

were incubated with the hepatocyte monolayers for up to 8 h and the low turnover compounds tolbutamide and diazepam were incubated for up to 24 h. The cell monolayers revealed no marked change in cell morphology after compound treatment, relative to vehicle control, after overnight incubations. We observed higher turnover with tolbutamide and diazepam in the hepatocyte monolayers as compared to that in suspensions. While *in vitro* CL_{int} values were statistically similar between fresh and cryopreserved monolayers, CL was slightly higher in fresh monolayers for phenobarbital, midazolam, tolbutamide, and diazepam (Table 13.2). This trend was more evident when the values were scaled to *in vivo* CL_{int} . Overall, our data are in line with other published studies comparing CL_{int} in fresh and cryopreserved human hepatocyte suspensions and monolayers [32,34,40,41].

Hepatic clearance (CL_H) can be estimated by three separate established models, each with different perceptions of liver physiology. These include the well-stirred model, parallel tube model, and dispersion model, all of which rely on inherent assumptions [30,42,43]. The fraction of drug unbound (f_u) is incorporated in the models to account for plasma protein binding. The present study utilized the well-stirred model to estimate CL_H with omission of the fraction unbound terms [32]. The following scaling factors were utilized in the equation: human liver weight = 22 g/kg body weight, hepatocellularity = 120×10^6 cells/g of liver, and hepatic blood flow = 20 mL/min/kg [32]. CL_H was compared to clearance observed in clinical studies. Predicted hepatic clearance was within the range (less than twofold) observed for *in vivo* clearance for phenobarbital, midazolam, dextromethorphan, and benzydamine in both fresh and cryopreserved hepatocyte suspensions. *in vivo* clearance for these compounds could also be predicted (less than twofold) from both fresh and cryopreserved hepatocyte monolayers. Interestingly, predictions were overestimated for low turnover compounds in the hepatocyte monolayers. Fresh monolayers overestimated tolbutamide CL by about 19-fold, while cryopreserved monolayers overestimated CL by about fourfold. A similar trend was observed with diazepam predictions where fresh and cryopreserved monolayers produced 13-fold and 5-fold overestimations in CL, respectively. These results are in agreement with a previously published study which reported overestimations of *in vivo* clearance for low clearance compounds using rat hepatocyte monolayers [39].

It is not immediately clear why fresh hepatocyte monolayers produced higher clearance than cryopreserved monolayers, as our prior studies have shown similar metabolic activity. Tolbutamide is metabolized by CYP2C9, while diazepam is metabolized by CYP2C19 and to a lesser extent, CYP3A. The CYP2C9-, CYP2C19-, and CYP3A-specific activities of the hepatocyte preparation used for this study did not differ significantly between the fresh and cryopreserved preparations (Fig. 13.1). If there was a difference in the two preparations in culture, this did not manifest in the predictions obtained for moderate and high turnover compounds. More studies are required with low turnover substrates and additional hepatocyte preparations to better understand the discrepancy between fresh and cryopreserved monolayers observed with tolbutamide and diazepam.

13.2.5 *In Vitro*–*In Vivo* Correlations

In vitro–*in vivo* correlation is the real measure of success for any given systematic approach relative to metabolic stability. Ito and Houston [44] reported a ninefold underestimation of *in vivo* CL_{int} for 52 drugs using published *in vitro* CL_{int} data derived

from human liver microsomes. A separate report examined 37 drugs in cryopreserved human hepatocytes from collated sources and reported a 4.5-fold underestimation in predicted clearance [45]. A recent study assessed compounds cleared primarily by glucuronidation in hepatocytes and microsomes. A poor *in vitro*–*in vivo* correlation was observed in microsomes, even after adding alamethicin and UDPGA in the incubations for Phase II metabolism [46]. In contrast, hepatocytes were proficient at catalyzing the phase II reactions. Overall, the general consensus is that primary hepatocytes predict hepatic clearance within two- to threefold of *in vivo* clearance values and are superior to microsomes for this purpose [35]. Currently, cryopreserved hepatocytes are the favorable model for metabolic stability studies because of the convenience of availability and because the same batch can be used multiple times, lessening concerns related to interdonor variability [35]. These results and others support the utility of cryopreserved human hepatocytes for metabolic stability and other metabolism studies (e.g., metabolic profiling and metabolite identification).

One of the main causes of discordance between *in vitro* and *in vivo* predictions and between laboratories that often goes unrecognized or underappreciated is the quality of the cell preparations—whether freshly isolated or cryopreserved. There are limited industry-wide acceptance criteria or established quality standards for primary human hepatocytes that has gained widespread adoption. As such, we propose the following criteria that can and should be considered whenever selecting a batch of cryopreserved hepatocytes for metabolic stability evaluations:

1. Consider the cellular and biochemical data that is provided with each batch of hepatocytes from the vendor. For example, most providers of hepatocytes include post-thaw viability and cell yield data, as well as the average specific activities for key P450 and Phase II enzymes, which should be within acceptable ranges. Average yields and viabilities vary somewhat between preparations and vendors but minimally they should be between 5.0 and 10.0 million cells per vial and >80%, respectively [38].
2. Information about “viability stability” over time should be provided by or obtained from the vendor to determine the suitability of preparations for suspension incubations. For instance, most metabolic stability studies require incubation times of 1–3 h. As such, it is important that the viability of the hepatocytes stays reasonably stable and does not drop more than 15–20% during that time period.
3. Average intrinsic clearance values of known substrates determined for each batch of cells should also be requested, if not provided. Typical values for low, medium, and high clearance compounds are available in literature and represent some guidance regarding the suitability of cryopreserved hepatocytes for metabolic stability assays.
4. Finally, in the event that accurate clearance values are needed for low turnover compounds, additional data about the attachment efficiency and percent confluence of the corresponding monolayers are the relevant parameters. On the basis of our experience, cryopreserved hepatocytes that exhibit >70% attachment efficiency after an initial 4–6 h attachment period generally are suitable for metabolic stability studies, with the prerequisite that suitable intrinsic clearance values are obtained for prototypical substrates during the subsequent 12- to 24-h culture period.

13.3 METABOLIC PROFILING AND METABOLITE IDENTIFICATION

13.3.1 Metabolic profiling

Metabolic profiling is the qualitative measure of the parent compound, the metabolites and their intermediates in response to actions by drug-metabolizing enzymes in biological systems. The measurement and interpretation of the metabolite profile from biological samples (typically primary hepatocytes or hepatic microsomes *in vitro*; and urine, serum, bile, or tissue extract, *in vivo*) provide a view of the exposure that a particular species has had, or will have, to the xenobiotic. The metabolism of drugs is a complex process involving one or more phase I and phase II enzyme systems. In discovery, the potential half-life of compounds is ranked based on metabolic stability, whereas in preclinical development, *in vivo* rodent and nonrodent species are used for allometric scaling to extrapolate to the human. Metabolic profiling is very useful in selecting the right preclinical nonrodent species for safety and PK assessments. For this, it is essential to choose the species with metabolites that are similar to what is expected in humans. Reasonably similar metabolites in *in vitro* systems support the relevance of a particular animal species to the assessment of a potential human risk. Moreover, knowledge of differences between a preclinical species and humans (e.g., a toxic metabolite in a particular preclinical species but not in humans) could aid in interpretation of clinical data. If there are major differences in the metabolites between the test species and humans, this would reduce the confidence in these studies as predictors of safety in humans. At the least, the species chosen should have all the major metabolites found in the human *in vitro* samples.

A decade ago, human liver microsomes were routinely used for metabolic profiling comparisons. However, this approach can lead to underprediction of metabolism, as the assumption that phase I oxidation is the major pathway of metabolism of the drug candidate is made. For example, in humans, ethinyl estradiol is predominantly metabolized by phase II metabolism into glucuronide and sulfate conjugates [47]. Human liver microsomes produce primarily the 2-hydroxyl metabolite, while human hepatocytes produce both the conjugated metabolites, similar to what is observed in human plasma samples. Microsomes underpredict ethinyl estradiol metabolism and fail to provide a true picture of metabolite exposure. Several such studies have demonstrated that while microsomes allow for the evaluation of specific phase I oxidative metabolites, intact fresh isolated or cryopreserved hepatocytes represent a more scientifically relevant experimental system, as these provide a more complete system to assess all possible metabolites. In cases where human hepatocyte samples develop a major metabolite not present in any of the animal cells, that metabolite has to be synthesized and exposed to the preclinical species, so that any potential toxicity can be assessed. These applications demonstrate the utility of hepatocytes for *in vitro* metabolic profiling and identification studies, as these have the capacity to develop phase I and phase II metabolites, similar to those formed *in vivo*.

Metabolic profiling studies are typically conducted over a short time period (2–4 h) using suspension hepatocytes that are placed in a nutrient-rich buffer or media, in a gently shaking, 37°C environment. In most cases, this is an appropriate format to conduct these experiments. In some cases, particularly for low turnover compounds, for example, *S*-warfarin and tolbutamide, this time is not sufficient for metabolism to completely occur. For these studies, we have found that similar to the intrinsic

clearance measurements, it is best to conduct overnight incubations. Since suspension hepatocytes do not thrive for more than 4 h in this environment, attached hepatocytes on a simple collagen substratum should be used, as these allows for a longer incubation and the formation of most of the possible metabolites [48].

13.3.2 Metabolite Identification

Structural identification of metabolites that have been generated by *in vitro* or *in vivo* evaluations is an integral part of preclinical and clinical drug metabolism studies. Literature indicates that the qualitative metabolite pattern of drug candidates obtained *in vitro* generally reflects that found *in vivo* [49]. *In vitro* knowledge of the structures of the major metabolites helps in predictions of the fate of drug candidates and enables the planning of timely strategies in cases where there may be toxicokinetics or hepatotoxicity issues in preclinical species or in the clinic.

The evaluation of all major human metabolites *in vitro* is emphasized in the FDA 2008 guidance “Safety Testing of Drug Metabolites.” The guidance recommends safety testing of drug metabolites that (i) account for more than 10% of parent drug AUC in human samples, (ii) are present only in human plasma, or (iii) constitute disproportionately higher levels in human samples as compared to preclinical species. Safety testing includes synthesis of the metabolite and exposure of the metabolite to a chosen preclinical species, followed by the conduct of toxicity studies. Conducting appropriate studies with hepatocytes before clinical evaluations could help in early attrition of drug candidates that have the potential to fail in the clinic due to metabolite-related toxicities.

Similar to metabolic stability and profiling measurements, a much clearer and more complete picture of the metabolites is obtained using hepatocytes versus microsomes. Improved tissue culture methodologies have enabled analysis of biliary metabolites *in vitro* [50]. By culturing primary hepatocytes in a 3D micropatterned collagen gel substrate configuration, Matsui *et al.* were able to quantify bile acids embedded in a microcavity with a diameter of 60–80 μm after directly recovering from the bile canaliculi of hepatocytes.

Previously, structural elucidation was typically performed later in preclinical development; however, over the past decade, this assessment has moved to Discovery in order to reduce later stage attrition. Owing to the larger number of compounds and the tighter time lines in Discovery, there is the need for immediately available and higher throughput methods (e.g., using cryopreserved hepatocytes and LC/MS/MS systems that utilize “smart” software to assist in the acquisition, identification, and structural characterization of metabolites). Although sensitivity can be a factor when using hepatocytes, substrate incubations at higher concentrations (i.e., 10–50 μM) and longer incubation times (i.e., 2–4 h) can circumvent this potential issue. Mass analyzers including time of flight, triple-stage quadrupole, ion traps, and Fourier transform mass spectrometry are increasingly sensitive. However, mass spectrometry (MS) alone is unable to adequately address all the caveats of structural elucidation. Additional information such as the site of biotransformation can aid structure activity relationship (SAR) to prevent undesirable PK effects when utilized in drug development. Where structural elucidation is needed, wet chemistry techniques combined with MS are useful including chemical derivatization, hydrogen/deuterium exchange, and hydrolysis.

Nuclear magnetic resonance (NMR) spectroscopy is also a valuable tool for structural characterization of metabolites. For example, LC/MS/MS was used to identify metabolites of retigabine in rat, dog, and human urine and other biological excreta [51]. While glucuronide metabolites were discovered in all three species, an additional acetylated metabolite was identified in rats and humans, which was absent in dogs. Using NMR, it was shown that the structures of retigabine metabolites in human and rat were similar across the *in vivo* urine samples and *in vitro* hepatocyte extracts. Similarly, novel metabolites of verapamil were identified in both primary human hepatocytes and human urine using LC/MS/MS and the structures elucidated using NMR [52]. All the above studies support the role of hepatocytes for metabolism studies, particularly for metabolic stability, profiling, and identification.

13.4 INHIBITION

13.4.1 Background

PK drug–drug interactions can occur when one drug alters the metabolism of a coadministered drug. Specifically, the metabolic route(s) of elimination, including most of those occurring via the P450 family of enzymes, can be inhibited by concomitant drug treatment leading to serious clinical drug–drug interactions. P450 inhibition is implicated in a majority of clinically relevant drug–drug interactions [53,54], as a P450 inhibitor can decrease metabolic clearance of a coadministered substrate drug and/or decrease formation of an active metabolite (or formation of a drug from a prodrug), resulting in decreased efficacy. This inhibition can be assessed in preclinical *in vitro* studies using hepatic microsomes and hepatocytes. The increase of plasma concentrations caused by drug interactions can be substantial, for example, the interaction between ketoconazole or itraconazole (CYP3A4 inhibitors) and triazolam (CYP3A4 substrate), which resulted in a 22- to 27-fold increase in triazolam exposure following coadministration with ketoconazole and itraconazole, respectively [55]. Unwanted effects are most obvious and expected when they involve drugs such as warfarin with a narrow therapeutic range resulting in an increase in plasma concentration.

Interactions involving enzyme inhibition have been responsible for the limited development potential, severe dosing restrictions, and even termination of development of many investigational drugs. If these interactions are not identified early in the development process, the result can be exposure to toxic drug levels in some patients, resulting in a black box warning on the product label or withdrawal of the drug from the market. A classic example of a drug interactions is with the nonsedating antihistamine Seldane® (terfenadine) and the common antibiotic erythromycin [56]. Patients treated with terfenadine along with erythromycin accumulated dangerously high blood levels of terfenadine because of the inhibition of CYP3A4 enzymes by erythromycin, resulting in potentially fatal arrhythmia. On the basis of this, the FDA issued a recall of Seldane® in 1997 and subsequently recommended that the potential of an investigative drug to be involved in drug–drug interactions be assessed relatively early in drug development.

Drugs that cause time- or metabolism-based inhibition of CYP450 enzymes may also result in potent, potentially toxic drug interactions. One such compound, mibefradil, a Ca^{2+} channel antagonist for the treatment of hypertension and

chronic stable angina pectoris caused serious drug–drug interactions, including rhabdomyolysis and renal failure with simvastatin, and symptomatic bradycardia with β -blockers [57,58]. Subsequently, mibefradil was found to be a potent inhibitor of CYP3A4, CYP2D6, and P-glycoprotein (P-gp) and a potent time-dependent inhibitor for CYP3A4/3A5 [59–61]. These serious adverse events resulted when mibefradil was coadministered with CYP3A4 substrates, likely because of time-dependent inhibition of CYP3A4 and mibefradil was withdrawn from the market a year after launch. Similarly, rofecoxib, a cyclooxygenase-2-selective NSAID, was withdrawn from clinical use in 2006 because of cardiovascular events, as rofecoxib moderately increased plasma concentrations and effects of theophylline [62] and the *R*-isomer of warfarin [63]. Therapeutic doses of rofecoxib increased plasma concentrations of tizanidine more than 10-fold, suggesting potent inhibition of CYP1A2 [64]. *In vitro* studies demonstrated that rofecoxib was a potent, mechanism-based CYP1A2 inhibitor and provided a mechanistic explanation for the interactions of rofecoxib with CYP1A2 substrates [65].

13.4.2 Experimental Approaches and Data

To understand the potential of drug candidates to cause PK-based drug–drug interactions via inhibition of drug-metabolizing enzymes, *in vitro* screens are employed to determine the extent and type of P450 inhibition. These assays typically use recombinantly expressed P450s, human liver microsomes, and human hepatocytes.

A majority of all enzyme inhibition studies are conducted using microsomes. More recently, the use of human hepatocytes to study P450 reversible and time-dependent inhibition is increasing, as primary hepatocytes provide an *in vitro* environment that closely resembles the human liver. CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4 reversible inhibition has been evaluated by known isoform-specific inhibitors in primary human hepatocytes [66]. Cryopreserved hepatocytes from a mixed pool of 10 adult human donors were used. Hepatocytes (2×10^6 cells/mL) were incubated with the test inhibitor and isoform-specific substrates: 50 μ M phenacetin (CYP1A2), 50 μ M coumarin (CYP2A6), 75 μ M tolbutamide (CYP2C9), 50 μ M *S*-mephenytoin (CYP2C19), 8 μ M dextromethorphan (CYP2D6), 50 μ M chlorzoxazone (CYP2E1), and 50 μ M testosterone (CYP3A4), for up to 2 h before terminating with organic solvent. The data set demonstrated that 10 μ M furafylline (CYP1A2), 50 μ M diethyldithiocarbamate (CYP2A6), 1 μ M sulfaphenazole (CYP2C9), 10 μ M omeprazole (CYP2C19), 1 μ M quinidine (CYP2D6), 100 μ M 4-methylpyrazole (CYP2E1), and 1 μ M ketoconazole (CYP3A4) inhibited metabolite production by 91.8%, 77.6%, 78.9%, 74.7%, 89.9%, 82.7%, 94.9%, respectively. Another report compares K_i values determined in rat microsomes and freshly isolated hepatocytes using six P450 inhibitors (miconazole, fluconazole, ketoconazole, quinine, fluoxetine, and fluvoxamine) [67]. These inhibitors were included in studies utilizing four probe substrates for CYP2C, CYP2D, and CYP3A enzymes (tolbutamide and phenytoin, dextromethorphan, and midazolam, respectively). All analyses were performed under initial rate conditions with respect to incubation time, microsomal protein content, or hepatocyte density. The K_i values determined in this investigation were in good agreement between microsomes and hepatocytes.

Time-dependent P450 inhibition has also been evaluated using cryopreserved human hepatocytes for six structurally diverse compounds known to exhibit time-dependent

inhibition [68]. CYP3A4 activities were determined after incubation with amprenavir, diclofenac, diltiazem, erythromycin, raloxifene, and troleandomycin. Human hepatocytes (0.5×10^6 cells/mL) were preincubated with and without time-dependent inactivators in 48-well plates for 1 h at a final volume of 250 μ L. At the end of the preincubation, 200 μ L aliquots were transferred to 96-well tubes, centrifuged, and the resulting pellet was washed and resuspended in cell culture medium containing midazolam, the probe substrate. The kinetic parameters (k_{inact} and K_I) associated with the inactivation of CYP3A4 in human hepatocytes were derived. In addition, the kinetic parameters of inactivation (k_{inact} and K_I) were measured using human liver microsomes. In general, this side-by-side comparison indicated that the microsome-based predictions overestimate the inactivation potency observed in hepatocytes for troleandomycin, erythromycin, raloxifene, and amprenavir. The discrepancies are likely related to metabolic stability, nonspecific binding, active membrane transport, or a combination of these factors. Therefore, these factors must be considered when microsomal inactivation parameters are used to predict inhibition-based drug interactions in intact cell systems. Time-dependent P450 inhibition has also been evaluated using human hepatocytes in cultures [69]. P450 activities were determined after incubation with tienilic acid, a prototypical inhibitor of CYP2C9 and erythromycin, troleandomycin, and fluoxetine, prototypical inhibitors of CYP3A4. Human hepatocytes were cultured on six-well collagen-coated plates and treated with varying concentrations of inhibitor (0.1, 1, and 10 μ M) for up to 48 h. At several time points during the incubation period, isoform-specific substrates in cassette format were added to each well. Aliquots were removed at various time points after addition of probe substrate, and the samples were quenched by the addition of organic solvent. Phenacetin deethylation, diclofenac 4'-hydroxylation, *S*-mephenytoin 4'-hydroxylation, bufuralol 1'-hydroxylation, and midazolam 1'-hydroxylation were used as selective probe reactions for CYP1A2, 2C9, 2C19, 2D6, and 3A4, respectively. The kinetic parameters (k_{inact} and K_I) associated with the inactivation of these enzymes in human hepatocytes were derived. In addition, the kinetic parameters of inactivation (k_{inact} and K_I) were measured using recombinantly expressed enzymes and human liver microsomes. In a side-by-side comparison, it was noted that the kinetic parameters obtained using human hepatocytes were in good agreement with those values derived using recombinantly expressed enzymes and human liver microsomes [69].

We have developed hepatocyte-based methods for the identification and quantification of reversible and time-dependent inhibition for CYP1A2, 2B6, 2C8, 2C9, 2C19, and 3A4, validating these assays with appropriate positive control inhibitors. Using single concentrations of the inhibitors investigated, 12–73% reversible inhibition was observed with the human hepatocytes (Table 13.3). Time-dependent inhibition in hepatocytes was assessed for a single concentration of inhibitor after a 30-min preincubation with hepatocytes and remaining activity compared to hepatocytes preincubated with vehicle only. At the inhibitor concentrations used, enzyme activities were reduced to 29–69% of control activity (Table 13.4). For CYP1A2, CYP2B6, CYP2C19, and CYP2D6, it was also observed that the 30-min preincubation with vehicle resulted in a reduction in activity of the enzymes as compared to coincubation alone (data not shown). The percentage of inhibition observed after 30-min preincubation with hepatocytes was compared to previous data generated in microsomes at identical inhibitor concentrations (Table 13.4). For all isoforms investigated, the inhibition in hepatocytes was similar to or less than the inhibition observed in human liver microsomes. This reduction in inhibition could be due to the contribution of cell

TABLE 13.3 Percentage of Reversible Inhibition in Cryopreserved Human Hepatocytes When Coincubated with Positive Control Inhibitors

Enzyme	Assay	Chemical Inhibitor	Inhibitor Concentration (μM)	Metabolic Activity in the Presence of Inhibitor (Percentage of Vehicle Control)
CYP1A2	Phenacetin <i>O</i> -deethylase	Furafylline	5	57.8 $\pm$ 1.7
CYP2B6	Bupropion hydroxylase	Thiotepa	20	53.0 $\pm$ 1.2
CYP2C8	Paclitaxel 6 α -hydroxylase	Quercetin	10	88.1 $\pm$ 3.3
CYP2C9	Diclofenac 4'-hydroxylase	Sulfaphenazole	6.25	37.3 $\pm$ 3.2
CYP2C19	(<i>S</i>)-Mephenytoin 4'-hydroxylase	Ticlopidine	1	26.8 $\pm$ 9.2
CYP2D6	Dextromethorphan <i>O</i> -demethylase	Quinidine	0.4	58.6 $\pm$ 14.3
CYP3A4/5	Midazolam 1'-hydroxylase	Ketoconazole	0.1	41.6 $\pm$ 8.3
CYP3A4/5	Testosterone 6 β -hydroxylase	Ketoconazole	0.1	60.2 $\pm$ 1.6

TABLE 13.4 Percentage of Time-Dependent Inhibition in Cryopreserved Human Hepatocytes When Preincubated with Positive Control Inhibitors

Enzyme	Substrate	Chemical Inhibitor	Inhibitor Concentration (μM)	Metabolic Activity in the Presence of Inhibitor (Percentage of Vehicle Control) Hepatocytes HLM	
CYP1A2	Phenacetin <i>O</i> -deethylase	Furafylline	1	29.3 $\pm$ 6.8	11.0–12.9
CYP2B6	Bupropion hydroxylase	Thiotepa	30	35.5 $\pm$ 2.1	10.9–12.4
CYP2C8	Paclitaxel 6 α -hydroxylase	Phenelzine	100	69.1 $\pm$ 6.0	25.4–45.2
CYP2C9	Diclofenac 4'-hydroxylase	Tienilic acid	3	58.3 $\pm$ 8.3	5.8–39.5
CYP2C19	(<i>S</i>)-Mephenytoin 4'-hydroxylase	Ticlopidine	0.5	39.4 $\pm$ 19.6	20.4–36.1
CYP2D6	Dextromethorphan <i>O</i> -demethylase	MDMA	10	55.4 $\pm$ 6.1	3.3–5.3
CYP3A4/5	Midazolam 1'-hydroxylase	Mifepristone	10	35.1 $\pm$ 5.5	5.6–22.7
CYP3A4/5	Testosterone 6 β -hydroxylase	Mifepristone	10	45.3 $\pm$ 4.5	6.2–9.5

Abbreviations: HLM, human liver microsomes; MDMA, 3,4-methylenedioxymethamphetamine.

membranes and/or uptake/efflux transporters, limiting the access of the inhibitors to the CYP enzymes. We also quantified the time-dependent inhibition of CYP3A4/5 by mifepristone, using midazolam 1'-hydroxylase activity as a marker for CYP3A4/5 activity. The inhibition parameters were determined to be $K_I = 23.1 \pm 2.1 \mu M$ and $k_{\text{inact}} = 0.101 \pm 0.003 \text{ min}^{-1}$. We demonstrated that hepatocytes can be used for the determination of reversible and time-dependent inhibition; however, it is difficult to prove that any inhibition observed is a result of metabolic activation. Further work will require a focus on conditions that would optimize a controlled environment for metabolic activation.

In another work reported by Mao *et al.*, cryopreserved human hepatocytes were used to compare the accuracy of enzyme inhibition predictions in a protein-free system combined with the fraction unbound in human plasma for inhibitor(s) with those obtained with protein-containing incubations [70]. Hepatocytes were incubated with or without CYP3A, CYP2C9, or CYP2D6 inhibitors at multiple concentrations, in human plasma or tissue culture media. The data indicated a general underprediction when using free systemic plasma concentrations. Hepatocytes suspended in the plasma proved to be a simple, accurate predictor of drug–drug interactions and superior to the protein-free approach [70].

Over the past 10–15 years, hepatocytes in primary culture have become widely recognized as the “gold standard” for predicting *in vivo* P450 induction in humans. In contrast, progress is just now being gained toward understanding the use of hepatocytes in inhibition/drug interaction studies. It is clear that the use of hepatocytes in these studies is advantageous in that the study of both phase I and phase II processes together with drug efflux and/or uptake and cellular accumulation can be assessed. Further studies should focus on further optimization of the experimental conditions and on understanding how the obtained results can be used in *in vitro*–*in vivo* predictions of drug–drug interactions mediated via P450 inhibition.

13.5 ENZYME INDUCTION

13.5.1 Background

Induction of hepatic drug-metabolizing enzymes can have significant consequences on the PK and toxicity of drugs. Chronic dosing of a compound that is an inducer can increase the expression of drug-metabolizing enzymes and transporters, which often leads to a concomitant increase in the activity of these clearance pathways. Consequently, any coadministered drug that utilizes these same clearance pathways will be more rapidly eliminated, resulting in lower drug concentrations and may become less effective. For example, rifampin can decrease the *in vivo* AUC of coadministered drugs by 70–90% (e.g., when coadministered with (*R*)-verapamil [71]), thereby significantly decreasing efficacy. Induction of P450s has been shown to result in toxicity by increasing reactive metabolite production or the CYP1A-mediated bioactivation of procarcinogens [72]. Induction effects are further complicated, as foods (e.g., grapefruit juice), cultural and lifestyle-related agents (e.g., alcohol and nicotine), and herbal supplements (e.g., St. John's Wort) can also induce enzyme activities. Chronic exposure to inducing agents has been shown to disrupt cellular homeostasis, leading to endocrine disruption, altered inflammatory response, and bone density loss [73–76]. Potent inducers such as rifampin and St John's Wort simultaneously upregulate multiple genes including CYP3A4, CYP2B6, UDP-glucuronosyltransferase (UGTs), and

glutathione-S-transferase (GSTs), as well as multiple transporters such as MDR1 (multidrug-resistant protein 1) and organic anion-transporting polypeptides (OATPs).

In most cases, the inducer directly or indirectly activates a cytosolic receptor complex causing it to translocate to the nucleus of the cell where the complex is converted to an active transcription factor, leading to increased transcription and translation of target genes that possess the corresponding DNA binding sequences in their promoter regions [77]. Although increased levels of these enzyme systems can occur by the stabilization of mRNA and/or proteins (e.g., induction of CYP2E1) [78,79], inductive events that lead to clinically significant changes in the clearance or bioactivation of drugs predominantly occur by a receptor-mediated process that causes increased production of an enzyme or other protein initiated at the level of gene transcription. These clinical effects can be predicted qualitatively *in vitro* using primary hepatocytes in sandwich culture.

In hepatocytes, the principle nuclear receptors, the aryl hydrocarbon receptor (AhR), the pregnane X receptor (PXR), and the constitutive androstane receptor (CAR) control the expression of key P450 enzymes involved in drug metabolism including CYP1A (AhR), CYP2B, CYP3A, and CYP2C subfamilies (PXR and CAR); the Phase II enzymes such as UGTs, glutathione-S-transferases, sulfotransferases; and transporters including MDR1, MRP2 (multidrug-resistance-associated protein 2), OATPs, and organic cation transporters (OCTs). Under appropriate culture conditions, primary hepatocytes retain relevant levels of the major drug-metabolizing enzymes, transporter proteins, nuclear receptors, and transcription factors, while thus far no immortalized or transformed hepatic cell line (e.g., HepG2, Fa2N4, or HepaRG) has been reported to contain the complete complement of enzymes, transporter proteins, and all corresponding receptor signaling cofactors. As such, primary hepatocytes in a sandwich configuration remain the model of choice for *in vitro* induction studies [14].

13.5.2 Experimental approaches

As stated above, under appropriate conditions, primary human hepatocytes express the biochemical and molecular machinery necessary to respond to enzyme inducers much as they would *in vivo* [80–82]. Currently, the most relevant culture model for induction is the sandwich culture system in which freshly isolated or cryopreserved hepatocytes are seeded on collagen, type I and allowed to attach and sandwich with an extracellular matrix overlay, typically hydrogels of collagen or Matrigel® [14,24,83]. This format provides a more “natural” environment for the hepatocytes, which retain liver-like cell morphology and form functional bile canaliculi [24,84,85]. In this culture configuration, the cumulative effects of metabolism, induction, time-dependent inhibition, and metabolite effects replicate the more steady-state-like effects on P450 activity and gene expression [86].

Tissue culture media also influences the morphology, integrity, and cellular function of hepatocytes. Our data indicate that Williams E Medium supports a higher basal CYP3A expression relative to the Dublecco’s modified Eagles medium/nutrient mixture Ham’s F-12 (DMEM/Ham’s F-12) and modified Chee’s media and, along with hepatocyte plating density, supports overall cell health and functionality [5]. Adult hepatocytes work best when cultured close to confluence ($\geq 90\%$) at the time of plating, as the cells redevelop normal epithelial morphology, junctional complexes, and bile canaliculi. When underplated at less than 50% confluence, hepatocytes

Figure 13.2 Effect of plating density on monolayer integrity and P450 enzyme activity in primary cultures of cryopreserved human hepatocytes. Photomicrographs of cryopreserved human hepatocytes at (a) 150%, (b) 100%, (c) 70%, and (d) 25% confluence. Bar graphs depict representative results of a single induction experiment with primary human hepatocytes cultured at five different seeding densities ($\times 10^5$ cells per well in a 24-well plate; $n = 3$). For the activity assays, hepatocytes were cultured for two days and then treated for three days with the prototypical inducers at the concentrations indicated in Table 13.3.

appear fibroblast-like after 24 h in culture and send out filopodial extensions. These hepatocytes have significantly lower CYP3A4 activity and responsiveness to prototype inducers than those plated at optimal confluence, although PXR levels remain equivalent (Fig. 13.2) [5]. Similar results have been obtained using freshly isolated and cryopreserved hepatocytes from the same donors. CYP1A1/2, CYP2B6, and CYP3A4 activities decreased with lower cell density, even though data was normalized for number of cells.

Fetal bovine serum enhances attachment and is only used for the initial attachment period of 4–6 h, as components in the serum can stimulate cell proliferation and loss of phenotypic expression [12]. Additives such as glucocorticoids (e.g., dexamethasone and hydrocortisone), insulin, selenium, and transferrin aid in the preservation of hepatocyte-specific morphology and function [12]. In most cases, albumin is included in media supplements at a final concentration of ~1 mg/mL, which affects both lipid and drug dispositions. After an initial recovery period in culture (24–48 h) during which hepatocytes are generally refractory to treatment with inducers, primary hepatocytes can be used for induction experiments and are typically incubated for two days with the test compounds when mRNA is the end point and for three days when enzyme activity is to be assessed. Cryopreserved hepatocytes can also be used for induction studies. For reasons not yet fully understood, a percentage of human hepatocyte preparations lose the ability to attach in culture after cryopreservation and thus cannot be used for induction studies. However, the hepatocytes that do attach efficiently and form a confluent monolayer retain the ability to induce, similar to fresh hepatocytes.

For induction assays, it is important to use healthy hepatocytes, appropriate culture conditions (medium and matrix), and positive control inducers at relevant concentrations that maximize inductive response while minimizing potential cytotoxicity, effective vehicle controls, appropriate time in culture, and the right complement of end points to allow effective interpretation of data. Table 13.5 provides a list of recommended positive control inducers based on our practical experience and understanding of various nuclear receptor pathways and their role in P450 transcription. A list of typical probe substrates for each relevant P450 isoform and their working concentrations are also provided.

As mentioned above, one of the most important considerations for achieving optimal outcomes from an *in vitro* induction study is the health and integrity of the hepatocyte monolayer. For example, often a very large fold change in mRNA or enzyme activity (e.g., >100-fold increase or >20- to 30-fold increase in CYP3A mRNA or activity, respectively) is not physiologically relevant to human liver *in vivo* and likely reflects an artificial response because of poor cell health or inappropriate culture conditions, which can result in diminished basal CYP3A expression and other liver-specific functions and regulatory pathways [5]. Conducting studies with compromised cultures with suppressed functionality may lead to misleading results, especially where metabolites of a new drug are the active species or toxic agents. Ideally, monolayers of primary hepatocytes, whether freshly isolated or cryopreserved, should be >80% confluent, show little or no sign of morphological deterioration (Fig. 13.3) over the study period (especially under control conditions), and exhibit at least 2.5-, 5-, and 10-fold increases in enzymatic activity over vehicle control for CYP3A4, CYP2B6, and CYP1A2, respectively, when treated with prototypical inducers [e.g., rifampicin, phenobarbital, and 3-methylcholanthrene (3-MC)]. Notably, induction of CYP3A4 enzyme activity greater than 10-fold for CYP3A4 is unusual and should serve as a red flag,

TABLE 13.5 Nuclear Receptors and the Corresponding Enzymes with the Positive Control Inducers and Substrates Typically Used for *In Vitro* Induction Studies with Human Hepatocytes

Receptor	Enzyme	Inducers (μM)	Substrate (μM)	Incubation (min)	Marker Metabolite
AhR	CYP1A1/2	3-Methylcholanthrene (2) Omeprazole (50) β -Naphthoflavone (25)	Phenacetin	15	Acetaminophen
CAR	CYP2B6	Phenobarbital (1000) CITCO (1) Phenytoin (50)	Brupropion	20	Hydroxybrupion
PXR	CYP3A4/5	Rifampin (10)	Testosterone	14	6 β -Hydroxytestosterone

Abbreviation: CITCO, 6-(4-chlorophenyl)imidazo[2,1-b][1,3]thiazole-5-carbaldehyde-O-3,4-dichlorobenzyl.

as this is not generally observed *in vivo* and could be due to artificially low basal activities that have resulted from poor cell health.

In addition to cell health, other considerations, such as the choice of vehicle control, positive control inducers, matrix and medium conditions (discussed above), and time of incubation, are also important for optimal results. The choice of vehicle control is often dictated by the solubility of the NCE being assessed for induction potential. Common solvents include dimethylsulfoxide (DMSO), methanol, and acetonitrile for most drugs, or simple isotonic buffers (e.g., phosphate buffered saline (PBS) and Hanks buffered salt solution (HBSS)) and cell culture medium for water-soluble compounds. Care should be taken in choosing the concentration of solvent vehicles, as they can contribute to an elevated baseline P450 expression and reduce the dynamic range of induction, as well as cause overt cytotoxicity at higher concentrations [5,80].

13.5.3 Experimental End Points

Induction of P450 enzyme expression can be assessed by evaluating mRNA, protein, and enzymatic activity. While the FDA 2006 draft guidance recommends evaluating activities of CYP1A1/2 and CYP3A4, a more recent commentary by the FDA recommends the addition of CYP2B6 activity to the screening regimen to account for activators of CAR [87]. The current FDA 2012 draft guidance recommends evaluating mRNA levels of all three enzymes, followed by CYP2C9 in cases where CYP3A4 induction is observed [2]. The newer guidance agrees with Fahmi *et al.* [88] that mRNA evaluation provides more appropriate *in vitro*–*in vivo* correlations, as the confounding effects of CYP inhibition, especially time-dependent inhibition, are not an issue. When there is no change, or more than a 40% increase in enzyme activity and mRNA expression relative to positive control inducer, the results are easy to interpret. Figure 13.4 depicts typical results with known inducers of CYP3A4, namely, rifampin, phenytoin, dexamethasone, and phenobarbital. In Fig. 13.4a, the results of an induction experiment where all compounds were treated at a final concentration of 10 μM are

Figure 13.3 Photomicrographs of hepatocytes following drug treatment. Cryopreserved human hepatocytes were treated with vehicle control (0.1% DMSO) or known toxicants such as chlorpromazine (CP), tamoxifen (TAM), or rotenone (ROT) at different concentrations (1, 10, or 100 μM) for 48 h and then assessed for changes in cell morphology using light microscopy.

Figure 13.4 Representative induction responses for CYP3A4 by prototypical inducers in human hepatocyte cultures. Hepatocytes were maintained for two days in culture without treatment followed by three consecutive days of treatment with (a) a single concentration (10 μM) or (b) multiple concentrations of rifampin (RIF), dexamethasone (DEX), phenytoin (PHN), or phenobarbital (PB). Hepatocytes from each treatment group were then harvested and microsomal CYP3A4 activity was determined using testosterone as substrate [71].

represented as a percentage of the positive control, which in this case was rifampin. At a single concentration, the compounds can be rank ordered according to their potency as an inducer and those causing an effect at or above 40% relative to the positive control would be designated for further evaluation.

However, it is important to note that all these agents cause significant induction of liver enzymes *in vivo* and that not all of them were tested at clinically relevant concentrations. As such, when tested over a broader range of concentrations in order to derive the entire concentration–response profile, it is clear that all the agents have the potential to cause significant induction of CYP3A4 (Fig. 13.4b). This underscores the importance of choosing the appropriate number and range of concentrations that are clinically relevant when conducting an *in vitro* study. The 2006 FDA guidance on drug–drug interactions recommended conducting activity assays and testing at concentrations equivalent to and an order of magnitude greater than the predicted or observed maximum plasma concentrations (C_{max}) of a NCE. The 2012 guidance recommends using multiple test compound concentrations and mRNA analysis as an end point to avoid the confounding effects of concomitant inhibition. Bear in mind that protein in the medium (e.g., albumin) can impact the free fraction of a drug and, therefore, using “total” drug concentrations often serve as a better guide when determining the relevant potency of an induction effect.

Determining the induction potential of test drugs is more complicated in cases where a decrease in enzyme activity is observed, which may or may not be accompanied by a drop in mRNA expression of the corresponding enzyme. There are three possible explanations for a decrease in enzyme activity after chronic treatment: (i) enzyme inhibition (as mentioned above), (ii) gene suppression, or (iii) cytotoxicity [89]. In the first case, enzyme inhibition can mask the induction response if a compound is both an inhibitor and an inducer of the same enzyme system(s). For example, the endothelin A receptor

antagonist CI-1034 does not cause significant induction of CYP3A4 activity in primary human hepatocyte cultures after three days of exposure. However, immunoblots and real-time polymerase chain reaction (PCR) analysis reveal significant increases in CYP3A4 mRNA and protein expression. CI-1034 was subsequently found to be a time-dependent (mechanism-based) inhibitor of CYP3A4. Notably, CI-1034 PK were linear in the clinical trials, even though this compound was metabolized predominantly by CYP3A4 [85]. The second cause of drug-induced decreases in P450 activity is when suppression of P450 gene expression occurs at the transcriptional level. A classical example of this effect occurred when children with a fever experienced central nervous system (CNS) toxicity after theophylline administration [90]. It has since been shown that proinflammatory cytokines downregulate many hepatic P450 genes, which appears to be mediated through the NF- κ B (nuclear factor kappa-light-chain-enhancer of activated B cells) pathway [91]. It is worth noting that the clinical manifestation of enzyme suppression can be similar to that of enzyme inhibition. As in the case described above, the cytokine-induced suppression of CYP1A2 activity in the infected children caused a decrease in theophylline clearance, which in turn led to increased blood levels of the drug and subsequent CNS toxicity.

The induction of P450s by prototypical inducers can also be attenuated at the transcriptional level, as is the case with CYP1A1 induction by tetrachloro-*p*-dibenzodioxin (TCDD) in HepG2 cells in the presence of microtubule-disrupting agents. The marked induction of CYP1A1 gene expression that normally occurs is blocked by colchicine and nocodazole because these agents disrupt microtubule-mediated signaling pathways and arrest the G2/M cell cycle [92]. Similarly, phenobarbital-induced CYP2B1 expression in primary rat hepatocytes is attenuated by docosahexaenoic acid. This effect occurs at the level of the nuclear receptor, as CAR accumulation in the nuclear fraction is decreased with a concomitant increase in the cytosolic fraction [93]. An earlier study determined that attenuation of CAR translocation and decreased subsequent binding to response elements in the *CYP2B1* promoter are involved in this chemical-induced down-regulation [94]. In the final case of drug-induced reduction in P450 enzymatic activity, the decreased enzyme activity can be caused by the onset of cytotoxicity. A number of compounds that are known to be potent P450 enzyme inducers produce “bell-shaped” concentration–response curves because of the fact that they begin to cause cytotoxicity at higher concentrations. For instance, both rifampicin and troglitazone exhibit this behavior when administered over prolonged periods to primary hepatocytes at concentrations of more than 50 μ M [82]. Accordingly, it is crucial to routinely conduct morphological assessments and, when a loss in enzyme activity is observed, to assess cytotoxicity in the monolayers using standard approaches such as cellular ATP content or lactate dehydrogenase (LDH) leakage.

When evaluating induction of P450 enzymes by a compound that is also a mechanism-based inhibitor, there may be no significant change in the activity of an individual isoform because of offsetting inhibition and induction, even though the compound is a nuclear receptor activator. In these cases, it is helpful to also evaluate the mRNA or protein concentrations to aid in the interpretation of results. P450 mRNA levels will not be affected by classical inhibition mechanisms that affect enzyme activity; however, they will decrease because of cytotoxicity or gene suppression. In most of these cases, the clinical end point is very difficult to predict. An example is the endothelin A receptor antagonist CI-1034, a compound metabolized predominantly by CYP3A4 that is also a metabolism-dependent inhibitor of this

enzyme. Analysis of enzyme activity in primary cultures after three days of treatment revealed no change in activity, while Western immunoblots revealed an increase in CYP3A4 immunoreactive protein and real-time PCR analysis demonstrated increases in CYP3A4 mRNA similar to that induced by rifampicin [85]. Interestingly, clinical data revealed linear PK, perhaps indicating that neither the inhibition nor the induction was significant *in vivo* or possibly, these processes negated each other. While this experimental end point could not be predicted *in vitro*, it is helpful to know the inhibition potential of a compound before conducting *in vivo* induction studies, so that appropriate study designs can be planned.

On the basis of our own experience and the reports of others, we recommend that an *in vitro* induction study minimally include (i) CYP1A, CYP2B6, and CYP3A enzymatic activity measurements; (ii) corresponding mRNA or protein determinations; (iii) a cytotoxicity end point (e.g., ATP content); and (iv) microscopic evaluation to monitor cell and monolayer integrity before and at the termination of an experiment.

13.5.4 *In Vitro/In Vivo* Correlations

It is now routine to consider a response of $\geq 40\%$ of the positive control activity *in vitro* as an indication of potential *in vivo* induction [95]. Many inducers produce a sigmoidal concentration–response profile (Fig. 13.4b) that is characteristic for a particular compound. The relevant characteristics to assess induction potential are the potency of the response (EC_{50} , effective concentration at half-maximal response), the efficacy (E_{max} , maximum effect or response), the no observable effect level (NOEL) or the highest no-effect concentration, and the relative shape of the concentration–response curve [96].

Similar to predictions of enzyme inhibition, a C_{max}/EC_{50} ratio of >1 indicates a likely inducer *in vivo* and a C_{max}/EC_{50} ratio of $0.1–1$ indicates possible induction, while a C_{max}/EC_{50} ratio of <0.1 indicates low potential for induction *in vivo*. Figure 13.5 demonstrates a simulated study with three compounds for which a $C_{max} < 1 \mu M$ would predict no induction potential, while a C_{max} of $8 \mu M$ would indicate significant induction for drug X and moderate induction for drugs Y and Z. Table 13.6 depicts the utility of using EC_{50} values for CYP3A4 induction and how the C_{max}/EC_{50} ratio relates to the predicted CYP3A4 induction potential. For example, while troglitazone and rosiglitazone have similar EC_{50} values for CYP3A4 induction, troglitazone is a potent clinical inducer [82,97,98] while rosiglitazone has no significant clinical induction effects [99]. Because of their differential selectivity for the therapeutic target (i.e., peroxisome proliferator-activated receptor (PPAR)), rosiglitazone is prescribed at a lower dose and the C_{max} is correspondingly lower and significantly below its EC_{50} value for PXR activation. As such, it can be important to understand and compare the selectivity and the therapeutic index between the on- and off-target effects of drug candidates. The lowest concentration at which the induction response occurs (NOEL) should also be considered [100].

According to the latest FDA guidance document on drug–drug interactions [2], the decision to conduct an *in vivo* drug–drug interaction study for an investigational drug as an enzyme inducer should be based on quantitative analysis of both *in vitro* and clinical PK data. Such analysis can be performed by a variety of algorithms and models including basic models, mechanistic static models, and more comprehensive dynamic models, for example, physiologically based pharmacokinetic (PBPK) models.

Figure 13.5 Simulated induction profiles of three hypothetical compounds (X, Y, and Z). Three distinct induction profiles were simulated to illustrate potential compound differences in potency (EC_{50}) while exhibiting similarities in efficacy (E_{max}) and NOEL.

TABLE 13.6 Relationship between *In Vitro* Potency and the Prediction of *In Vivo* Induction using the EC_{50} and Therapeutic Plasma Concentrations^a

Compound	EC_{50} (μM)	C_{max}/C_{ss} (μM)	$[I]/EC_{50}$	Induction Potential
Rifampin	0.8	14	17.5	Likely
Carbamazepine	0.8	25	28	Likely
Phenobarbital	125	40–180	0.3–1.5	Likely
Phenytoin	25	80	3.2	Likely
Troglitazone	3–5	7	2.3	Likely
Avasimibe	0.2	1–6	5–30	Likely
Rosiglitazone	5–10	0.3–1.2	0.06–0.12	Possible
Simvastatin	0.14	0.024	0.17	Possible
Lovastatin	1–5	0.008	0.008–0.02	Unlikely
Clotrimazole	1–5	topical	(inhibition)	Unlikely
Nifedipine	8	0.008	0.001	Unlikely

^aRef. 101.

Basic models have been predominantly used because they are simple and practical. These models are conservative, but in some cases, they eliminate the need for later clinical investigations of drug–drug interaction potential. For example, the cutoff value to decide whether further *in vivo* investigation of a drug as an inducer is needed is generally calculated based on the fold induction over a negative or vehicle control (e.g., fourfold or higher) or the percentage of induction relative to an appropriate positive control (e.g., $\geq 40\%$ of a positive control) [88,101].

As suggested before, comparison of induction response curves is more complex than simply determining any one of these parameters alone [101]. Whatever method is used to calculate the potential induction risk *in vivo*, once a compound is found to be positive in an *in vitro* hepatocyte induction assay, drug interaction clinical trials are generally warranted, but it is rare that these results would stop the development

of a compound. However, attrition sometimes occurs if the compound showed potent induction effects, especially if these were expected and interfered with cotherapies. Often multiple options are pursued when considering the implications of a positive *in vitro* induction response. Most often extra drug–drug interaction (DDI) studies are requested in the clinical trials (recommended by the FDA) or other PK properties of the compound are assessed to determine the overall induction potential. For example, some of the other properties considered were protein binding, clearance, and bioavailability, all of which influence the induction response *in vivo*. Of course, another option which is often pursued is that the induction data is provided back to the discovery chemists in an attempt to minimize or eliminate the inductive properties of new molecules.

13.6 HEPATOBIILIARY TRANSPORT

13.6.1 Background

Transporters in the hepatocyte basolateral and apical membrane are responsible for carrier-mediated processes involved in the uptake, biliary secretion, and systemic reabsorption of xenobiotics, their metabolites, and endogenous compounds. Hepatic clearance is a function of transporter and drug-metabolizing-enzyme-mediated processes. Hepatic clearance starts with transport into hepatocytes (phase 0) by passive diffusion through the cell membrane or by active transport. In hepatocytes, transport is mediated by basolateral membrane organic anion transporters (OATs) including OAT2 and OAT5; OATP1A2; OATP1B1; OATP1B3; OATPB2B1; the organic cation transporter OCT1; and the sodium taurocholate cotransporting polypeptide (NTCP). All these transporters are retained in the membranes of primary sandwich-cultured hepatocytes (Figure 13.6). Phase III is transporter-mediated elimination of the intact drug and metabolites (if any) from the hepatocytes via ATP-dependent apical or basolateral membrane efflux transporters and in some cases, bidirectional organic anion or cation transporters. Apical membrane hepatobiliary transporters involved in xenobiotic transport include the MDRs such as MDR1, MRP1, MRP2, the breast cancer resistance protein (BCRP), and the bile salt efflux pump bile salt export protein (BSEP) [102]. These efflux transporters are maintained in primary hepatocytes in sandwich culture after two to three days of plating. Drugs that are eliminated unchanged via the bile may undergo enterohepatic circulation and may be reabsorbed from the intestine [103]. The BSEP mediates the efflux of conjugated and unconjugated bile salts into the bile, and inhibition of this transporter by a drug could result in hepatotoxicity [104]. Multiple transporters mediate the excretion of compounds from hepatocytes back into systemic circulation via basolateral membrane efflux transporters (phase III). As shown in Fig. 13.6, the outwardly directed efflux transporters include the ATP-binding cassette (ABC) proteins MRP1 and MRP3. Thus, multiple membrane transporters in hepatocytes work in concert with the drug-metabolizing enzymes to mediate hepatic drug clearance. These transporters play a key role in drug clearance and may contribute to drug–drug interactions.

13.6.2 Transporter-mediated drug interactions

Similar to the drug-metabolizing enzymes, drug–drug interaction involving hepatic membrane transporters can occur by competition for the same substrate-binding site of

Figure 13.6 Schematic of uptake and efflux xenobiotic transporters in human hepatocytes.

the transporter, or tight or allosteric binding leading to inhibition of transporter activity, or by change in expression level of transporters. This has the potential to alter the blood concentration–time profiles of drugs, leading to elevated levels of a coadministered compound. Evaluating the substrate potential of a drug candidate for hepatic transporters *in vitro* is beneficial when these organs are the drug target. For example, the hepatitis C drugs α -interferon and *S*-acyl-2-thioethyl esters or the HMGCoA inhibitors must achieve adequate concentrations in the liver for pharmacological activity. Evaluating potential substrates of efflux transporters also aids in predictions of drug clearance when compounds are predominantly eliminated into the bile, for example, atorvastatin. Evaluating drug interactions with transporters *in vitro* during drug discovery can lead to improved predictions of clinical drug–drug interactions. Hepatic transporters are now implicated in adverse interactions that were earlier attributed to the drug-metabolizing enzymes. *In vitro* studies with mibefradil revealed CYP3A4 inhibition potential, but the clinical outcome was significantly larger than what was predicted from the *in vitro* studies [105]. A few years later, mibefradil was found to inhibit P-gp as well [106], and the additive effect of this interaction explained the underprediction of the effect on PK of coadministered therapeutics. Similarly, the effect of grapefruit juice on fexofenadine PK, which was initially attributed to CYP3A4, was later reported to involve the inhibition of OATP-mediated fexofenadine uptake [107]. Digoxin, which has been used as a P-gp substrate in both *in vitro* and *in vivo* studies and is the FDA probe substrate of choice for both preclinical and clinical drug interactions studies, is now

reported to be a substrate for hepatic OATP transporters as well, and there are ongoing discussions on the appropriateness of this compound as a P-gp substrate. Other examples of adverse drug interactions attributed to hepatic transport proteins involve the statins, as coadministration of gemfibrozil with pravastatin, simvastatin, lovastatin, and cerivastatin significantly increases statin AUC and $C_{\max}$ [108,109]. Inhibition of the basolateral membrane hepatic uptake transporter OATP1B1 by gemfibrozil contributes to these drug interactions [110,111]. While the above clinical transporter-mediated drug interactions were unexpected, with current strategies, *in vitro* transporter assays can be used to identify the transport proteins involved in drug disposition, thereby aiding drug interaction predictions, so that fewer adverse events occur in the clinic. Some of these methodologies are discussed in the following section.

In addition to drug–drug interactions, hepatic transporters also play a role in hepatotoxicity. Drug-induced hepatotoxicity is a major problem in drug development and there is growing evidence that inhibition of bile acid transporters is a contributing mechanism of liver toxicity [112]. Multiple apical and basolateral membrane hepatic transporters work in concert to transport bile acids and xenobiotics from blood to bile via the hepatocytes, and inhibition of any of these processes could result in adverse events. Hepatotoxicity is a significant cause of compound attrition. Several drugs (bosentan, troleandomycin, troglitazone, glyburide, tacrine, and erythromycin) have exhibited no or minimal hepatotoxicity in preclinical *in vivo* experiments and resulted in significant increases in liver function enzymes in clinical trials, or in the market when exposed to a wider patient population. Drug-mediated inhibition of active canalicular transport of biliary components is a contributing cause of this hepatotoxicity [104,113]. Inhibition of the apical membrane bile transporter BSEP has been shown to result in cholestasis and hyperbilirubinemia [84,114], and there is evidence that inhibition of OATP1B1 can result in hyperbilirubinemia [115]. MRP4 may play an important role in minimizing hepatotoxicity, as this transporter is upregulated when BSEP is downregulated [116].

In many cases, drugs that cause cholestasis are preferentially eliminated (>50%) via the biliary pathway, and this hepatotoxicity is likely associated with drug-mediated inhibition of active canalicular transport of bile components [113,114]. Since the transporters that participate in biliary drug elimination also transport endogenous bile components, the potential for inhibition of bile acid and drug efflux from the liver could result in an increase in drug and bile acids retained in the liver over time. Many of these drugs have now been found to be substrates for active liver-transporter-mediated uptake and efflux into the bile canaliculi using primary hepatocytes [84,112,117]. Table 13.7 lists some of the major hepatic transporters involved with hepatotoxicity and drug–drug interactions. In an earlier study using six macrolide antibiotics, we showed that drugs with greater hepatotoxic risk are stronger inhibitors of taurocholate transport in cultured human hepatocytes [84]. In addition to primary hepatocytes, hepatocytes in suspension can also be used to evaluate hepatic transport.

13.6.3 Experimental approaches

13.6.3.1 Hepatic Couplets. The hepatocyte couplets are consist of two hepatocytes with a distinct bile canalicular space between these. This model allows for the evaluation of drug uptake and biliary elimination. The advantage of the couplets is that these are polarized and have a sinusoidal membrane interacting with the media/buffer and an apical bile canaliculus, which is the sealed lumen between the two adjacent

TABLE 13.7 Major Human Hepatic Transport Proteins and Known Substrates and Inhibitors

Transporter	Gene Name	Substrates	Inhibitors
NTCP	SLC10A1	Taurocholate, glycocholate, taurochenodeoxycholate and tauroursodeoxycholate, estrone-3-sulfate, BSP	Rifampin, rifamycin SV, glibenclamide, cyclosporin A, indomethacin, ritonavir, saquinavir, efavirenz, troglitazone
OATP1B1	SLCO1B1	Bile acid, BSP, DHEAS, DPDPE, E217 β G, estrone-3-sulfate, ouabain, bilirubin, bilirubin glucuronides, pravastatin, rosuvastatin, atorvastatin, rifampin, olmesartan, bosentan, fexofenadine, methotrexate	Estrone-3-sulfate, gemfibrozil, methotrexate, ketoconazole, cyclosporin A, rifampin, rifamycin SV, clarithromycin, indinavir, ritonavir, CI-1034
OATP1B3	SLCO1B3	bile acids, BSP, DHEAS, digoxin, DPDPE, E217 β G, estrone-3-sulfate, ouabain, bilirubin, rifampin, pravastatin, rosuvastatin, pitavastatin, telmisartan, fexofenadine, olmesartan, bosentan, nafcillin, β -lactam antibiotics	cyclosporin A, rifampin, ketoconazole, clarithromycin, ritonavir, verapamil, T-3095, T-3157, CI-1034
OATP2B1	SLCO2B1	Benzylpenicillin, BSP, DHEAS, estrone 3-sulfate, rosuvastatin, atorvastatin	Cyclosporin A, estrone-3-sulfate, methotrexate, CI-1034
BSEP	ABCB11	Taurocholate, glycocholate, taurochenodeoxycholate, tauroursodeoxycholate and pravastatin	Bosentan, glyburide, troglitazone, rifampin, rifamycin SV, glibenclamide, cyclosporin A, ritonavir, saquinavir, efavirenz, rosiglitazone

Refs 84,85,87,102,114, and 118–123.

hepatocytes [124]. The application of couplets is limited because the substrate must contain a fluorescent chromophore to be quantitated. While the data obtained from these studies is valuable, isolating and working with hepatic couplets requires skill and is very low throughput, further accounting for the limited transporter studies with this model over the past decade.

13.6.3.2 Primary Hepatocytes. Hepatocytes in suspension, attached to tissue culture dishes or in primary sandwich culture are good models of hepatic clearance, uptake, efflux, biliary excretion, transporter-mediated drug interactions, induction, and hepatotoxicity. The contribution of transporter-mediated uptake to hepatic CL was recognized when H_{CL} was consistently underpredicted for many series of chemotypes using just metabolic stability for the calculations. Factoring in transporter-mediated hepatic uptake

along with metabolic clearance using hepatocytes in suspension improved these predictions [125]. From our experience, hepatic uptake via a particular transporter can be effectively assessed with single-transfected cell lines (e.g., HEK-293 cells transfected with OATP1B1 or OATP1B3 or OATP2B1), yet this system is less effective in extrapolating H_{CL} because of the significant differences between transporter types and content in the cell lines and in hepatocytes [126]. Therefore, plated and suspension hepatocytes have become the system of choice for quantitative information on hepatic drug uptake.

13.6.3.3 Suspension Hepatocytes. Hepatocytes in suspension can be used for uptake experiments shortly after isolation from the liver, or for up to 24 h, if cells are kept in the appropriate buffer on ice. Gene expression in human hepatocytes in suspension after isolation is similar to the liver of origin, with minor changes likely due to the absence of significant numbers of other hepatic cell types, for example, Kupffer cells and cholangiocytes [127]. Hepatic uptake studies typically measure the rate of appearance of substrate into cells after a relatively short incubation period, in most cases from 10 s to 3 min. After incubation, hepatocytes are centrifuged in microfuge tubes through an oil layer (that does not allow passage of the buffer and traps lipophilic compound that may be on the outer cell membrane) into a layer of 2 N NaOH or KOH or cesium chloride, for digestion [128]. This bottom layer along with the digested trapped hepatocytes is counted or analyzed by MS. This methodology has provided robust, mechanistic data that can successfully predict the *in vivo* clearance of drugs [39]. Cryopreserved hepatocytes can be successfully used for these studies, and there is evidence to suggest that transporter gene expression in human hepatocytes in suspension is not affected by cryopreservation [127]. In this study, gene expression for primary human hepatocytes after cryopreservation was similar to the liver of origin and included transport, lipid metabolism, phase II metabolism, protein processing, degradation, and recycling. This indicates that both freshly isolated and cryopreserved hepatocytes can be used for transporter-mediated uptake studies.

We have evaluated uptake in multiple lots of cryopreserved human hepatocytes and found up to a 10-fold difference between donors. For example, taurocholate CL was typically between 12 and 48 $\mu\text{L}/\text{min}/\text{million cells}$, digoxin CL varied from 0.6 to 4.5 $\mu\text{L}/\text{min}/\text{million cells}$, and estradiol-17 β -glucuronide (E217 β G) CL varied from 0.5 to 5 $\mu\text{L}/\text{min}/\text{million cells}$ (Fig. 13.7). We also prepared five donor pools of cryopreserved human hepatocytes. This protocol includes rapidly thawing out the hepatocytes, pooling cells from five different preparations, subjecting these to a percoll gradient to remove dead cells and refreezing these in liquid nitrogen as per our standard cryopreservation procedure. Since these cells undergo two freezing steps, we were uncertain how well the membrane transporters continued to function. We studied uptake in this preparation and compared the data to standard cryopreserved cells and also to literature data. As shown in Fig. 13.7, the pooled cells could be used adequately to assess membrane transport of taurocholate, E217 β G, and digoxin.

13.6.3.4 Primary Culture. Hepatocytes cultured on plastic culture dishes or on rigid collagen dedifferentiate and rapidly lose hepatic transport activity and other liver-specific functions. Owing to this, transporter-mediated uptake studies utilizing hepatocytes cultured in this configuration should be conducted as soon as possible, either right after attachment (~ 4 h before plating) or within 24 h of plating.

Figure 13.7 Uptake clearance in cryopreserved primary hepatocytes in suspension. For these experiments, either single-cryopreserved (1–5) or pooled cryopreserved (6–7) hepatocytes were used in suspension. Hepatocytes were thawed and resuspended in a buffer, and uptake of the prototypical substrates ($1 \mu\text{M}$ each) of BSEP (taurocholate), OATP transporters (estradiol-17 β -glucuronide), and OATP1B3 (digoxin) is assessed by the oil spin method. Data represent a single experiment for each lot conducted in triplicate.

In the sandwich culture configuration, hepatocytes polarize, retain membrane transporters and drug-metabolizing enzymes (albeit at varying concentrations over time), and establish functional bile canaliculi [24,84]. The bile canaliculi formed in sandwich culture (Fig. 13.8) have morphological and biochemical characteristics similar to those observed *in vivo*, including microvilli in the bile canaliculi, localization of function-specific drug-metabolizing enzymes and relocation of the major uptake and efflux transporter to the appropriate cell membrane [129,130]. Using this model, apical and basolateral membrane transport of a drug and metabolites can be evaluated.

Figure 13.8 Effect of cyclosporine on bile salt transport into hepatic canalicular spaces. Carboxy-2',7'-dichlorofluorescein diacetate (CDFDA) staining in the presence (a and c) and absence (b and d) of $10\ \mu\text{M}$ cyclosporine. (a) and (b) are fluorescence images and (c) and (d) are phase contrast images at $10\times$ magnification. Bile canaliculi are formed in sandwich culture and CDFDA is transported into the hepatocytes and out to the bile via active transport mechanisms. Cyclosporine is an inhibitor of these transporters and prevents the transport of CDFDA into the canalicular spaces.

Sandwich-cultured hepatocytes have been used to evaluate MDR1-, MRP2-, MRP3-, and BSEP-mediated hepatobiliary disposition and hepatotoxic potential of drugs successfully [84,129,130].

13.6.3.5 Cryopreserved Hepatocytes. In sandwich culture, cryopreserved hepatocytes preserve the drug-metabolizing enzymes, nuclear receptors, and major uptake and biliary transporters [131,132] and are used for transporter studies as well. Hepatocytes can also be used for evaluating induction of transporters by drugs, aiding in the prediction of drug disposition and potential drug–drug interactions [133,134]. When cryopreserved and cultured appropriately, hepatocytes in sandwich culture reveal good morphology with distinct bile canaliculi. The function of multiple uptake (OATPs and NTCP) and efflux (MRP2, MRD1, and BSEP) transporters was found to be similar to fresh hepatocytes [135]. We have evaluated biliary excretion in multiple preparations of human hepatocytes and compared these with fresh hepatocytes and demonstrated essentially similar values (Figs. 13.9 and 13.10).

13.6.3.6 Small interference RNA (siRNA/RNAi). At this time, there are no specific inhibitors of hepatic transporters. For this reason, when conducting studies in hepatocytes, the contribution of a specific transporter to the uptake or efflux of a drug

Figure 13.9 Biliary efflux in three preparations of freshly isolated sandwich-cultured human hepatocytes. Human hepatocytes were placed in primary sandwich culture for six days and uptake and biliary efflux of taurocholate, estradiol-17β-glucuronide, and digoxin monitored. Biliary clearance and the biliary clearance index were calculated. BEI, biliary excretion index.

candidate cannot be evaluated using probe substrates or chemical inhibitors. When the contribution of a single transporter needs to be evaluated, small interference RNA (siRNA) could provide the data required. This involves specifically knocking out the mRNA of interest by introducing antisense RNA into hepatocytes, causing degradation of the corresponding complementary mRNA in a gene-dependent manner, followed by loss of the target protein. siRNA has been used successfully to assess transporter activities between wild-type cells and those in which the transporter of interest has been silenced [136,137]. In sandwich-cultured rat hepatocytes, the mrp2 and mrp3 proteins have been specifically knocked down, one at a time using siRNA and resulted in 45–60% decreases in the biliary excretion index of carboxydichlorofluorescein (CDF)

Figure 13.10 Taurocholate accumulation in six preparations of freshly isolated sandwich-cultured human hepatocytes. Human hepatocytes were placed in primary sandwich culture for five to six days and uptake and biliary efflux of taurocholate monitored. Biliary clearance and biliary clearance index were calculated. Filled bars are hepatocytes incubated in a physiological buffer containing the divalent cations Ca^{2+} and Mg^{2+} ; stippled bars are hepatocytes incubated in the absence of Ca^{2+} and Mg^{2+} . BEI, biliary excretion index; SEM, mean standard error.

[136]. In another study, the efflux transporter Bcrp was knocked out using Ad-si01Bcrp in rat hepatocyte monolayers and the contribution of this transporter to the biliary excretion of some drugs were evaluated [137]. We have conducted preliminary experiments with cryopreserved human hepatocytes in our laboratory and have successfully knocked down OATP1B1, OATP1B3, and OATP2B1 mRNA one at a time without affecting the other two transporters (Fig. 13.11).

13.6.4 *In Vitro/In Vivo* Correlations

To predict potential transporter-mediated drug interactions, the degree of inhibition can be calculated as per the method of Shitara *et al.* [138,139]. If the test compound is a substrate for hepatic transporters, *in vitro* drug–drug interaction studies with the NCE and likely coadministered therapeutics, known to be the inhibitors of the specific transporter pathway(s), can be conducted to calculate the degree of inhibition in an appropriate transporter system. If historic or experimentally derived *in vitro* data indicates that the test compound is an inhibitor for one or more hepatic transporters, *in vitro* drug–drug interaction studies with the test compound and likely coadministered therapeutics, known to be substrate of the specific transporter pathway(s), can be conducted. The degree of interaction (R) can be estimated by the following equation.

$$R = 1 + \frac{fu \times I_{in,max}}{K_i}$$

Figure 13.11 siRNA suppression of OATP1B1, OATP2B1, and OATP1B3 in primary human cryopreserved hepatocytes from a single donor. Cryopreserved human hepatocytes were thawed and plated on collagen-coated plates and allowed to attach for 5 h before siRNA transfection. Stealth Select 3 RNAi™ sets for OATP1B1, OATP2B1, and OATP1B3 were used. Lipofectamine RNAiMax™ was complexed with Stealth Select siRNA™, and cells were exposed to siRNA overnight. mRNA was isolated 48-h post transfection and cDNA synthesis and real-time PCR with EXPRESS One-Step Superscript® qRT-PCR Universal. Data is represented as percentage of nontreated cells.

$I_{in,max}$ is the unbound inhibitor concentration (C_{max}) at the entry point of the organ (e.g., in the hepatic portal vein for the liver or the renal artery for the kidney), f_u the blood unbound fraction, and K_i the inhibition constant. In most cases, an IC_{50} value is utilized instead of the K_i . The potential for drug–drug interaction is minimal if the calculated R value is close to one and increases as the value of R decreases. These *in vitro* studies can identify potential inhibitors and/or substrates to use in clinical drug–drug interaction studies. The contribution of the inhibition of the transporter-mediated hepatic uptake of cerivastatin by cyclosporine A was used to explain clinical PK interactions between these drugs. Further studies from this laboratory [140] showed the effect of cyclosporine A on the *in vivo* disposition of cerivastatin in rats could be explained using primary rat hepatocytes. *In vitro* and *in vivo* correlation analysis revealed that this PK interaction could be quantitatively explained by the inhibition of transporter-mediated hepatic uptake.

13.7 HEPATOTOXICITY

13.7.1 Background

Drug-mediated hepatotoxicity in humans can be categorized as hepatocellular, cholestatic, and mixed hepatocellular/cholestatic [141]. Hepatotoxicity is the most common single adverse event resulting in product label warnings, failure to market or withdrawal after reaching larger patient populations. Halothane was one of the first compounds to be withdrawn from the market (early 1960s) because of the hepatotoxicity and caused massive centrilobular liver necrosis and hepatic failure [142]. In this, and most other cases, the failure of preclinical animal studies to predict human drug-induced liver toxicity has been attributed to interspecies differences,

some of which are not yet characterized [143]. In attempts to better understand these events, many *in vitro* and *in vivo* models have been developed.

13.7.2 Experimental Approaches

Before the development of successful *in vitro* model systems, researchers relied exclusively on preclinical *in vivo* animal models for predicting human toxicity. While there has been limited success with *ex vivo* isolated/perfused animal livers, researchers have come to the logical conclusion that the best indicator of human hepatotoxicity is to use human cells. Human liver slices have been successfully used over the past two decades for biochemical and histochemical characterization of cellular damage [144,145]. An advantage of liver slices in estimating hepatotoxicity is the integral cellular complement and connections [146]. Limiting factors to this technology, however, include the diffusional barrier that obstructs substrate access to the metabolizing enzymes, as well as oxygen depletion in the slice's inner core [147]. These variables can significantly affect data interpretation in toxicity studies.

The use of isolated human primary and immortalized hepatocytes has removed the limitations associated with liver slices. Since immortalized cells divide, they can be placed in primary culture and utilized over multiple passages. Some view this as an advantage over using fresh primary cells, which are dedifferentiated and can only be used a single time. However, because of the genetic shift associated with repeated passage, most immortalized liver cells lack metabolizing and transporting capabilities, which play a significant role in drug-induced liver toxicity [148]. For this reason, immortalized cell lines may be less or more susceptible to drug-induced toxicity than primary hepatocytes and therefore less predictive of *in vivo* human hepatotoxicity [149,150]. The newer-generation hepatoma cell line HepaRG expresses mRNA encoding various nuclear receptors, P450 enzymes, and phase II enzymes in similar levels as in three- to five-day human primary hepatocyte cultures and may thus serve as an adequate model for early cytotoxicity screening [151].

The optimization of isolating, freezing, thawing, and culturing primary human hepatocytes has resulted in human hepatocytes gaining acceptance as models for cytotoxicity and genotoxicity [83,152]. While both fresh and cryopreserved hepatocytes are used successfully for studying hepatotoxicity, the issues of availability and reproducibility with fresh hepatocytes can be overcome by using cryopreserved cells [153]. Furthermore, interspecies differences can be evaluated simultaneously *in vitro* using cryopreserved hepatocytes from multiple species. Cryopreserved hepatocytes can be characterized for their metabolic capabilities and this information can be incorporated into bioactivation-related hepatotoxicity studies [14]. For example, cytotoxicity studies have demonstrated that CYP2D6-mediated bioactivation of 3,4-methylenedioxymethamphetamine (Ecstasy) forms a metabolite that is more than 100-fold more toxic than the parent compound in primary hepatocytes [154]. Depending on the type/duration of toxicity, one must consider using cell suspensions for short-term toxicity (up to 5–6 h incubations) versus plated hepatocytes for long-term toxicity. Composition of the tissue culture media can also affect the response of isolated hepatocytes to cytotoxic agents. Medium plays a role in preserving liver cell function, and it can also interact with the test drug or its metabolites [83]. Since many compounds bind to proteins, the addition of proteins to the culture medium can greatly decrease toxicity induced by a chemical [155].

13.7.3 *In Vitro* Hepatotoxicity Assays Used in Primary Hepatocytes

Cytotoxicity is a cascade of cellular events that begins with early intracellular changes in homeostatic mechanisms. Necrosis is estimated to be nearly 50% of all drug-related hepatic damage and is associated with membrane leakage, cell swelling, decrease in ATP utilization, and nuclear disintegration [156]. Another major distinction of necrosis is the association of influx of inflammatory cells which then release reactive oxygen species. Conversely, apoptosis is an active process, associated with cell shrinkage, nuclear fragmentation, increased mitochondrial function, pinocytosis, and the formation of apoptotic bodies [157]. Therefore, choosing the appropriate combination of apoptotic and necrotic end points is necessary so that toxicity is not missed.

Light microscopy can be used to observe the morphological effects on cell shape, accumulation of vacuoles and lipid droplets, blebbing, and cell attachment/detachment. When necrosis occurs in hepatocytes *in vivo*, the associated plasma membrane leakage can be detected biochemically by assaying plasma (or serum) for liver cytosol-derived enzymes, including LDH and transaminases aspartate aminotransferase (AST) and alanine aminotransferase (ALT). These three enzymes are used clinically as biomarkers of hepatic damage and are measured *in vitro* in primary hepatocyte cultures to assess for the potential for clinical hepatotoxicity. Figure 13.12 illustrates the concentration-dependent LDH leakage following 48-h exposure of three classical hepatotoxicants: chlorpromazine (CP), tamoxifen (TAM), and rotenone (ROT). Significant LDH leakage was detected following exposure to 100 μM CP, 100 μM TAM, and 10 and 100 μM ROT. Sometimes, detrimental changes in cell morphology precede membrane leakage. Figure 13.3 is a morphological assessment of these treatments. While 1 μM ROT caused minimal LDH leakage, cell imaging via light microscopy shows the beginning signs of toxicity, that is, increased intracellular granularity and diminished brightness of the nuclei. Visual toxicity was detected in all treatment groups that caused LDH leakage. We recommend that cell morphology always be assessed when using cell-based toxicity assays. LDH leakage might sometimes miss the earlier stages of toxicity and an additional toxicity end point is ATP determination. The utilization of ATP energy

Figure 13.12 Hepatotoxicity as measured by LDH leakage. Cryopreserved human hepatocytes were thawed and plated using CellzDirect complete thawing, plating, and maintenance media. Hepatocytes were treated with multiple concentrations of known cytotoxicants chlorpromazine (CP), tamoxifen (TAM), and rotenone (ROT) for 48 h before assessing LDH leakage.

is significantly decreased as result of necrosis, and there are simple, quick bioluminescence assays available, which are based on luciferase's requirement for ATP in emitting light [158].

Tetrazolium salts such as MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) are widely used for detecting redox potential of hepatocytes in cytotoxicity assays. These assays are based on the principle that continued cell growth maintains a reduced environment, while inhibition of growth maintains an oxidized environment. Reduction related to growth causes these tetrazolium salt REDOX (reduction–oxidation) indicators to change from the oxidized form to the reduced form. Following reduction, these water-soluble, colorless compounds form uncharged, brightly colored but nonfluorescent formazans, which can be quantified by standard spectrophotometric techniques. Newer generations of tetrazolium salts, such as XTT (2,3-bis (2-methoxy-4-nitro-5-sulfophenyl)-5-[(phenylamino)carbonyl]-2*H*-tetrazolium hydroxide), MTS (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium), and Presto Blue, have been determined more sensitive and less labor intensive than MTT [159–161].

Biochemically, apoptotic cells are distinguished from necrosis by fragmentation of the genome and cleavage or degradation of specific cellular proteins. Early stage apoptosis involves the breaking apart and fragmentation of nuclear chromatin, followed by degradation of the nuclear envelope and nuclear blebbing. These processes result in the formation of micronuclei, which can be easily visualized through staining. Nucleic acid stains such as Hoechst 33342 are readily taken up by cells during the initial stages of apoptosis, whereas cell-impermeant dyes such as propidium iodide and ethidium bromide are excluded [162]. Later stages of apoptosis are accompanied by an increase in membrane permeability, which allows propidium iodide to enter cells [163]. Detection of DNA fragmentation using electrophoresis has been found to be one of the most reliable methods for detecting apoptosis [164]. DNA extracted from apoptotic cells, separated by gel electrophoresis, and stained with ethidium bromide reveals a characteristic ladder pattern of low molecular weight DNA fragments [165]. TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling) assays are commonly used for detecting DNA nicks in apoptotic cells. Once the cells are fixed, DNA strand breaks can be detected *in situ* with an avidin or streptavidin conjugate [166]. Additional apoptosis assays are based on protease activities. Another characteristic of the early stages of hepatic apoptosis is the disruption of active mitochondria. These events include changes in the membrane potential and alterations to mitochondrial oxidation–reduction potential [167]. Fluorescent mitochondrial stains such as calcein and rhodamine 123 provide easy and reliable detection of the loss of mitochondrial membrane potential that occurs during apoptosis [168,169].

Depletion of protein thiols by alkylation or oxidation is an important initial event in the development of drug-induced hepatotoxicity. Glutathione-depleting agents such as diethylmaleate and paracetamol have demonstrated the role of glutathione in the detoxifying process through addition of and by measurement of binding of metabolites to cellular proteins [170]. These metabolites can lead to the production of reactive oxygen species and are associated with idiosyncratic toxicity, especially in the liver. Hepatocytes have the capacity to eliminate these reactive oxygen species, but in some situations, such a capacity is limited and oxygen free radicals can interact with cellular proteins, lipids, or nucleic acids. The detection of these reactive metabolites in *in vitro* systems such as hepatocytes can be used to assess the potential for toxic response

such as adduct formation and immune system intervention. Some compounds can mediate toxicity directly (e.g., paracetamol), while others trigger adaptive immune responses in susceptible patients (e.g., halothane and dihydralazine) [171]. Human hepatocyte cultures have been used for predictions of immunoallergic hepatitis (e.g., clometacin) [172]. Other toxic phase II metabolites such as acyl-glucuronide and acyl-CoA thioester conjugates of carboxylic acid drugs have been studied extensively since several NSAIDs, for example, zomepirac, benoxaprofen, and ibufenac are associated with hepatotoxicity [173].

DNA adducts can also cause mutations and induce chromosome or chromatic-level aberrations [174,175], and this can be estimated in primary hepatocytes by the unscheduled DNA synthesis (UDS) method, which requires small numbers of cells and is accepted by testing and regulatory agencies [176]. Interestingly, the UDS response is usually quite similar in human and rat hepatocytes, whereas other species show marked differences in their responses [177].

13.7.4 Future *In Vitro* Toxicity Models

Newer *in vitro* approaches based on understanding how nuclear receptors and gene signaling play a role in hepatotoxicity are being developed [178]. One major goal is to develop an entire panel of functional toxicity assays (e.g., apoptosis, oxidative stress, and mitochondrial function) and gene expression targets. Sophisticated databases have been developed to analyze data across multiple donor preparations and identify the “firing sequence” of toxicants across the functional assays and gene targets. This technology will allow for clustering of new drugs/chemicals in the hepatocyte-derived database to predict toxicity potential and probe mode-of-action relative to well-characterized “toxicants.” For several years, microarrays have distinguished toxic and nontoxic drugs (i.e., troglitazone vs. rosiglitazone and pioglitazone) by measuring changes in protein expression levels in hepatocytes [179]. However, limitations in throughput and sensitivity of these more traditional approaches often neglect to incorporate full concentration- and time-related responses. Newer approaches, such as US Environmental Protection Agency (EPA)-driven “ToxCast” allow for standardizing primary hepatocyte data analysis across donors and profiling chemical response with *in vivo* end points [180,181]. Gene-to-gene correlations can provide insight into previously unknown regulation as well as validate an assay by confirming correlations known in current literature.

There is evidence that hepatocytes in monoculture are not predictive of toxicological responses such as fibrosis and cytokine-mediated cytotoxicity. Nonparenchymal cells, including Kupffer, stellate, and sinusoidal endothelial cells, contribute only 6.5% to the liver volume but 40% to the total number of hepatic cells. Many hepatocyte functions are regulated by substances released from neighboring nonparenchymal cells [182,183] (e.g., Kupffer cells) and secrete potent mediators of the inflammatory response (reactive oxygen species, eicosanoids, nitric oxide, carbon monoxide, tumor necrosis factor- α (TNF α), and other cytokines), thereby controlling the early phase of liver inflammation [178]. These enzyme and cytokine mediators may significantly affect liver-metabolizing enzymes, as well as damage hepatocytes. For example, clinical studies have shown that interleukin-2 (IL-2, a cytokine currently used to enhance immune responses in cancer and HIV patients) causes significant suppression of CYP3A4 [184]. While hepatocyte monocultures failed to predict this phenomenon, it was reproduced in Kupffer

cell/hepatocyte cocultures, concluding that the IL-2-mediated suppression is modulated indirectly through Kupffer cells [183]. Similarly, stellate cell/hepatocyte cocultures have been used to predict hepatotoxicity. In the normal liver, stellate cells store vitamin A, control turnover of extracellular matrix, and regulate the contractility of sinusoids. However, damage to hepatocytes under toxic conditions, such as drug-induced hepatitis, alcohol consumption, and biliary obstruction, activates transformation of quiescent stellate cells into myofibroblast-like cells that play a key role in the development of hepatic fibrosis [185]. These findings have shown that hepatocyte cocultures with non-parenchymal cells better represent liver physiology, and these represent the future of *in vitro* hepatotoxicology research.

13.8 FDA DRAFT GUIDANCE

FDA issued a draft drug–drug interaction guidance in 2012 that recommends evaluating potential interactions between an investigational new drug and the most likely to be coadministered drugs, during drug development. This document provides guidance on identifying the principal routes of elimination, the contribution of enzymes and transporters to drug disposition, and characterization of mechanisms of drug–drug interactions.

13.8.1 Drug-Metabolizing Enzymes

The enzymes recommended for evaluation are CYP1A2, 2B6, 2C8, 2C9, 2C19, 2D6, and 3A and UGTs. The UGTs mentioned in the document are UGT1A1, 1A3, 1A4, 1A6, 1A9, 2B7, and 2B15. If these enzymes do not explain metabolism of a compound, additional enzymes such as CYP2A6, CYP2J2, CYP4F2, CYP2E1, or non-CYP enzymes including monoamine oxidase (MAO), flavin monooxygenase (FMO), xanthine oxidase (XO) and alcohol/aldehyde dehydrogenase should be evaluated on a case-by-case basis. Recombinant enzymes are suggested for determination of the specific enzymes involved in metabolizing a drug candidate, microsomes for the inhibition assays, and primary hepatocytes for the induction evaluations.

13.8.1.1 Inhibition Studies. The decision tree for metabolism-based drug–drug interaction studies recommends evaluating *in vitro* metabolism for the major drug-metabolizing enzymes using human tissues. If the test compound is a substrate of an enzyme that is responsible for $\geq 25\%$ of its systemic clearance, clinical studies need to be conducted with strong inhibitors and a significant interaction would trigger studies in subjects with different genotypes and clinical studies with less strong inhibitors that are likely to be coadministered. In cases where multiple enzymes cumulatively are responsible for $\geq 25\%$ of the systemic clearance of an investigational drug, the potential of complex DDI should be evaluated. When an interaction is observed, clinical studies are to be conducted with the most sensitive, specific substrates. Positive results would trigger additional studies with substrates that are likely to be coadministered to patients and when appropriate, mechanistic modeling used to make dosage adjustment recommendations. When glucuronidation is responsible $\geq 25\%$ of total metabolism, *in vitro* studies with UGT recombinant enzymes should be conducted. These will help plan clinical studies for UGT1A1

using specific inhibitors such as atazanavir, or with more general inhibitors such as probenecid.

The potential for drug interactions with metabolites that are present at $\geq 25\%$ of parent drug AUC is also recommended. The guidance also suggests that metabolic drug–drug interactions be explored for investigational drugs that are not eliminated significantly by metabolism, as these drugs could inhibit or induce a coadministered drug’s metabolic pathway. An emphasis has been placed on model-based evaluations of interactions, including basic model for initial assessments to mechanistic models such as PBPK modeling. Total test drug concentrations are to be used for all calculations.

13.8.1.2 Induction. FDA suggests evaluating CYP1A2 (positive control: omeprazole), CYP2B6 (positive control: phenobarbital), and CYP3A (positive control: rifampicin), using mRNA *in vitro* and if CYP3A4 induction is observed, CYP2C9 (positive control: rifampicin), using ≥ 3 separate human hepatocyte preparations. If the increase in mRNA is greater than predefined threshold values using relevant positive and negative controls, or if the calculated *R* value is less than $1/1 \cdot I$ (i.e., 0.9), then the investigational drug is likely a CYP inducer and area under the curve ratio (AUCR) of a sensitive probe substrate should be calculated using a mechanistic static model. Positive results would determine the need for clinical evaluations with appropriate probe substrates. Total test drug concentrations are to be used for all calculations.

13.8.2 Transporters

The guidance recommends that all investigational drugs are evaluated *in vitro* using transfected cell lines, to determine the substrate potential for the efflux transporters P-gp and BCRP and the uptake transporters OATP1B1 and OATP1B3, when the hepatic pathway is significant ($\geq 25\%$ of total clearance), and the renal transporters OAT1, OAT3, and OCT2, when renal active secretion is $\geq 25\%$ of total clearance. All investigational small molecule drug candidates are to be evaluated for potential inhibition using known substrates for P-gp (e.g., digoxin), BCRP (e.g., rosuvastatin), OATP1B1/OATP1B3 (statins), OAT1 and OAT3 (e.g., methotrexate and tenofovir), and OCT2 (e.g., metformin). For inhibition studies, total test drug concentrations are to be used for calculations of efflux and hepatic transporters and free drug concentrations for the renal transporters.

13.9 SUMMARY

One of the greatest challenges for pharmaceutical scientists is the accurate prediction of *in vivo* behavior of new compounds from *in vitro* data. The prospect of accurately predicting a drug’s metabolic clearance, organ toxicity, and drug–drug interaction potential *in vivo* is still an evolving process. However, our current scientific understanding of the biological processes that dictate overall drug disposition and toxicity has greatly improved our ability to assess the likelihood that a particular drug will cause serious adverse effects or drug–drug interactions *in vivo* [85,89,186]. The pharmacodynamic effects of therapeutic agents cannot be predicted accurately without consideration of the respective PK and toxicokinetics. A number of biological and physiological parameters are involved in determining the total disposition of a particular compound and therefore

will partially determine the exposure of drug to a particular enzyme, transporter, or nuclear receptor site [187,188]. It is important to always compare the *in vitro* concentrations for all metabolism and transporter-based assays with target potency to understand the selectivity. One aspect we have not discussed in this chapter is protein binding. This is because we have yet to figure out when *in vitro* protein binding significantly affects *in vivo* predictions. Continued efforts to define and model these parameters and their impact on drug disposition *in vivo* are needed for proper management of patient drug therapies.

In conclusion, many initial concerns regarding the use of primary hepatocytes for predicting the hepatic clearance, major metabolites, hepatotoxicity, and potential drug interactions of NCEs have been addressed. Primary hepatocytes represent a tremendously versatile preclinical tool for evaluating the overall hepatic disposition of drugs in humans. The response of human hepatocyte cultures to treatment with various compounds (both positive and negative modulators) reflects that observed *in vivo* with regard to both enzyme specificity and potency of the effect. In addition, primary cultures of human hepatocytes have the distinct advantage of exhibiting species-specific profiles and other related responses. However, because of our ever-expanding knowledge of the biological processes involved in overall drug disposition and the creation of more physiologic-based culture platforms, we are faced with a corresponding challenge (and expectation) to improve the accuracy of our *in vivo* predictions as well as the speed at which studies are performed. As such, our future endeavors must find ways to meet the current and future demands that face the pharmaceutical and chemical industries in this new millennium of drug discovery and development.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to Patricia Pawlowski (Life Technologies, Durham, NC) for providing the photomicrographs, to Dr. Pieter Annaert (Catholic University of Leuven, Leuven, Belgium) and Erica Deibert (Life Technologies, Durham, NC) for the hepatocyte transporter data, to Laura Vozza-Brown (Life Technologies, Carlsbad, CA) for help with the siRNA experiments.
